INVESTOR IN PEOPLE

The Patent Office
Concept House
Cardiff Road
Newport
South Wales
NP10 8QQ

I, the undersigned, being an officer duly authorised in accordance with Section 74(1) and (4) of the Deregulation & Contracting Out Act 1994, to sign and issue certificates on behalf of the Comptroller-General, hereby certify that annexed hereto is a true copy of the documents as originally filed in connection with the patent application identified therein.

In accordance with the Patents (Companies Re-registration) Rules 1982, if a company named in this certificate and any accompanying documents has re-registered under the Companies Act 1980 with the same name as that with which it was registered immediately before re-registration save for the substitution as, or inclusion as, the last part of the name of the words "public limited company" or their equivalents in Welsh, references to the name of the company in this certificate and any accompanying documents shall be treated as references to the name with which it is so re-registered.

In accordance with the rules, the words "public limited company" may be replaced by p.l.c., plc, P.L.C. or PLC.

Re-registration under the Companies Act does not constitute a new legal entity but merely subjects the company to certain additional company law rules.

Request for grant of a patent

(See the notes on the back of this form. You can also get an explanatory leaflet from the Patent Office to help you fill in this form)

The Patent Office

Cardiff Road
Newport
South Wales
NP10 8QQ

1. Your reference

NJH/MP6190474

2. Patent application number

(The Patent Office will fill this part in)

24 DEC 2003

0330019.1

3. Full name, address and postcode of the or of each applicant (underline all surnames)

DAVID JOHN POWELL
33 FISHPOND LANE
EGGINTON
DERBY
DE65 6JH

Patents ADP number (if you know it)

If the applicant is a corporate body, give the country/state of its incorporation

9779308001

4. Title of the invention

APPARATUS AND METHOD FOR CONTROLLING DISCHARGE LIGHTS

5. Name of your agent (if you have one)

"Address for service" in the United Kingdom to which all correspondence should be sent (including the postcode)

MEWBURN ELLIS
York House
23 Kingsway
London WC2B 6HP

Patents ADP number (if you know it)

109006

6. Priority: Complete this section if you are declaring priority from one or more earlier patent applications, filed in the last 12 months.

Country

Priority application number
(if you know it)

Date of filing
(day / month / year)

7. Divisionals, etc: Complete this section only if this application is a divisional application or resulted from an entitlement dispute (see note d)

Number of earlier UK application

Date of filing
(day / month / year)

8. Is a Patents Form 7/77 (Statement of inventorship and of right to grant of a patent) required in support of this request?

NO

Answer YES if

- a) any applicant named in part 3 is not an inventor, or
- b) there is an inventor who is not named as an applicant, or
- c) any named applicant is a corporate body.

Otherwise answer NO (See note d)

Patents Form 1/77

Accompanying documents: A patent application must include a description of the invention. Not counting duplicates, please enter the number of pages of each item accompanying this form:

Warning

After an application for a patent has been filed, the Comptroller of the Patent Office will consider whether publication or communication of the invention should be prohibited or restricted under Section 22 of the Patents Act 1977. You will be informed if it is necessary to prohibit or restrict your invention in this way. Furthermore, if you live in the United Kingdom, Section 23 of the Patents Act 1977 stops you from applying for a patent abroad without first getting written permission from the Patent Office unless an application has been filed at least 6 weeks beforehand in the United Kingdom for a patent for the same invention and either no direction prohibiting publication or communication has been given, or any such direction has been revoked.

Notes

- If you need help to fill in this form or you have any questions, please contact the Patent Office on 08459 500505.
- Write your answers in capital letters using black ink or you may type them.
- If there is not enough space for all the relevant details on any part of this form, please continue on a separate sheet of paper and write "see continuation sheet" in the relevant part(s). Any continuation sheet should be attached to this form.
- If you have answered YES in part 8, a Patents Form 7/77 will need to be filed.
- Once you have filled in the form you must remember to sign and date it.
- Part 7 should only be completed when a divisional application is being made under section 15(4), or when an application is being made under section 8(3), 12(6) or 37(4) following an entitlement dispute. By completing part 7 you are requesting that this application takes the same filing date as an earlier UK application. If you want the new application to have the same priority date(s) as the earlier UK application, you should also complete part 6 with the priority details.

APPARATUS AND METHOD FOR CONTROLLING DISCHARGE LIGHTS

The present invention relates to apparatus and methods
5 for controlling discharge type lights, such as
fluorescent lights and the like.

Discharge lights operate by causing electricity to flow
between two electrodes separated by an inert gas such as
10 argon or krypton with a small amount of a conduction
element such as mercury or xenon which may be in both
liquid and vapour form. Electrical conduction, through
the inert gas, is instigated by supplying a voltage to
the electrodes of sufficient magnitude to cause electrons
15 to migrate through the inert gas from one electrode to
another. While travelling towards the anode (positive
potential) electrode, electrons will typically collide
with atoms of the conduction element with sufficient
kinetic energy to ionise its vapour atoms and also
20 vapourise the elements liquid atoms, thereby producing
positive ions and further free electrons within the gas.
Thus, a gas plasma of positively and negatively charged
particles is produced. Electrons of the plasma continue
to stream towards the anode of the electrodes while the
25 much heavier positive ions of the plasma are accelerated
towards the cathode thereof. This streaming of electrical
charge sustains an electrical discharge within the
discharge light.

30 Collisions within the plasma between electrons and
ionised atom of the conducting element causes the
emission of light photons, from the plasma as post-
collisional ions relax from an excited state (caused by
collision) to a ground state. In this way, electrical

energy is converted efficiently into light energy within a discharge light.

The vast majority of common or garden discharge lights
5 take the form of fluorescent tubes as often found in
homes and work places. Such fluorescent tubes employ the
discharge process described above. The inert gas
contained within fluorescent tubes is typically mercury.
This component is caused to emit Ultra-Violet (UV)
10 radiation as a result of the collisional process
described above. A phosphorescent material coating the
inner surface of the glass envelope containing the
discharge plasma absorbs such UV radiation and re-emits
the energy received thereby as visible light.

15

Once the gas within the envelope of the discharged light
has been rendered conductive and thereby exists in a
plasma state, subsequent conduction through the gas self-
sustains the plasma. However, the initial voltage
20 required to induce this state of conduction is typically
very high and is known as the "strike" voltage. As soon
as the gas within a discharge light begins to discharge,
the effective electrical resistance of the now conductive
plasma drops rapidly. The effective resistance of the
25 plasma behaves as a so-called "negative resistor" so
called because as the voltage across the electrodes of
the lamp increases, the effective resistance of the
plasma decreases thereby creating an increase in
discharge current through the plasma which further lowers
30 the effective resistance and so increases the discharge
current, and so on. This would end in a maximum current
for minimum resistance causing the discharge light to
dramatically fail were the current not controlled in some
way.

A ballast circuit is typically employed to control the current passing through the discharge light in order to mitigate the run-away effects of "negative resistance".

5 At its simplest, a ballast circuit comprises a simple inductor placed in series electrical connection between the power supply and the discharge light. The impedance of the inductor effectively matches changes in the load resistance of the discharge light such that changes in
10 the effective resistance of the discharge light are compensated for by resultant changes in the impedance of the inductor. In this way the ballast circuit inductor acts as a power regulator regulating the power supplied to the discharge light.

15

Unfortunately, since the impedance of the ballast circuit inductor is reactive, when it draws energy from an alternating-current (AC) power source the phase of the AC current drawn thereby lags the phase of the AC voltage by
20 90°. Consequently, power is wasted by not matching the phase of the current and voltage of the power signal drawn by the ballast circuit and discharge light in use.

As a consequence of this inefficiency, commercial
25 electricity suppliers have, for some time, required large consumers of power to pay an additional consumer charge for consuming power in such phase mismatched conditions. Additionally, in an attempt to reverse the aforementioned phase mismatch, most domestic discharge light fittings
30 are supplied with a simple corrector device comprising a capacitor connected in parallel across the power input terminals of the discharge light. The reactive impedance of a capacitor exhibits phase properties which are opposite to those of an inductor, namely, current will be

drawn by the capacitor at a phase 90° in advance of the voltage drawn thereby when supplied by an AC power source. Hence, an appropriate capacitor may assist in nulling the phase lag induced by the ballast circuit inductor.

Unfortunately the capacitance of a typical corrective capacitor is subject to considerable variation over time in use. It is quite normal for discharge lights such as fluorescent lights to be in service for as long as 20 years. It is highly probable that within this time period a corrective capacitor will have degraded, thereby changing the value of its capacitance, or will have failed completely. As a result, the corrective properties and purpose of the corrective capacitor C will be degraded or completely lost thereby resulting in the highly inefficient powering of the discharge light.

The traditional ballast for a fluorescent discharge light is known as an electromechanical or type 'D'. With this type of ballast the fluorescent discharge light switching-on typically proceeds as follows. Power is applied via a ballast inductor L at the frequency of the mains power source. When the voltage is first applied to the circuit, the lamp does not initially operate. Consequently, the mains supply voltage appears across the "starter" via the inductor and the light cathodes. The "starter" consists of bi-metallic contacts sealed within a small discharge bulb with inert gas filling such as argon or neon. The mains voltage causes a glow discharge within which heats up the bi-metallic contacts causing them to close. This completes the circuit and allows pre-heat current to flow through the inductor and both cathodes. Since the glow discharge within the starter has

now ceased the bi-metallic contact cool down and open. Because the inductance of the inductor tries to maintain current flow (i.e. it resists changes in current), the voltage across the lamp rises rapidly and strikes the light. If it does not, the starter's contacts close again and the cycle repeats. Once the light has started, the inductor controls the current and voltage to the correct levels. The current supplied to the light under normal running conditions is enough to keep the cathode heaters hot and emitting electrons without the need for separate heater supplies. Since the lamp's running voltage is much lower than the mains voltage, there is now not enough voltage to cause the glow discharge in the starter, so it remains open circuit.

15

A further example of known discharge light control is the next generation of ballast called electronic or type 'A', so called because it uses a much more complex active control circuit made up of discrete electronic components. These work by converting the mains supply voltage into a DC supply source and then inverting this back into a high frequency AC supply by means of some form of transistorised switching circuit (an inverter). The output of this inverter stage is then driven via a much smaller high frequency ballast inductor L into the discharge light. This process is much more efficient than the type 'D' because electronic ballasts replace the starting and inductive elements of the conventional system. The effect is to increase the operating frequency of the ballast above the 50 or 60Hz determined by the mains to typically to a few tens of kHz. This has two main advantages, firstly the gas in the tube does not have time to deionise between current cycles, which leads to lower power consumption. Secondly the inductor

required to generate a large enough voltage to ionise (strike) the tube is smaller, and so generates less resistive losses. However, the electronic solution is more complex and has a higher initial cost, this is
5 eventually paid back by the savings in energy over time.

Fluorescent discharge lights may be "dimmed" thereby to controllably vary the radiant power output of the fluorescent light. Current dimming methods simply vary
10 the voltage supplied to the fluorescent discharge light via the ballast circuit associated with it thereby to reduce the total power available to the inductor of the ballast and ultimately across the fluorescent discharge light. This method requires the use of expensive extra
15 control components/stages and delivers a generally poor dimming effect. In particular, the range of variability of the irradiated power output of the discharge light (i.e. the "dimming range") is rather small since reducing the voltage applied to the discharge light runs the grave
20 risk of causing plasma "drop-out" whereby the voltage becomes insufficient to maintain the plasma state within the discharge light.

The new electronic fluorescent ballast, type 'A', are
25 more efficient in their ability to generate light output power for input power consumed and it is to these types that the present invention is particularly (though not exclusively) directed. All present implementations of these electronic ballasts follow the exact same
30 principles. One of the effects that they generally all exhibit is that there is an element of the source supply AC component superimposed on the DC power signal supplied to the inverter. These fluctuations in the DC power level are subsequently delivered to a discharge light via a

ballast circuit. The DC fluctuations appear as "ripples" superimposed upon each half-cycle of the AC power signal. These ripples typically produce a flickering affect in the radiant power output of the discharge light. This is most undesirable. Additionally, such variations, when present during the dimming of discharge light by reducing the voltage applied to it as discussed above, may cause the applied voltage to be momentarily insufficient to maintain the plasma state of the discharge light and thereby cause plasma "drop-out". This is most undesirable. It is also desirable to achieve the highest possible general power to light version efficiency in order to facilitate the lowering of total consumed mains/national power. This is of major importance to lower international CO² levels.

The present invention aims to overcome at least some of the deficiencies in the prior art identified above. Compared with the traditional type 'D' ballast the type 'A' ballast achieves an improvement of some 15-20% in power consumption. The present invention aims to improve that figure by a further 10% (e.g. in basic operation mode) and greater than 25% (e.g. in active ambient light controlled mode), as shall be discussed below. In the following, a reference to "AC power signal" includes a reference to either of the AC electrical current and the AC electrical voltage signal of a power source.

The present invention in its first aspect, at its most general proposes, when supplying AC power (e.g. from an inverter) to a discharge light via a ballast circuit formed by a resonant circuit, controlling the frequency of the AC power signal so as to operate below the natural resonance frequency of the ballast circuit.

A beneficial consequence of operating the discharge light ballast at below-resonance frequencies is that the inductor element is forced past its saturation point and therefore effectively becomes a low resistive path to the inverter output energy. This means that the losses associated with inductor magnetisation are much reduced so saving energy that would otherwise be lost as heat. It also affects the profile of the resultant current waveform delivered to the discharge light (e.g. fluorescent light) itself. With current methods these will naturally result in close approximate sinusoidal current shapes due to the resonant action of the ballast, with the present invention in its first aspect, operation below resonant frequencies results in an increase in harmonic products of the current, and therefore this creates a more "square" wave current profile that closer matches the most efficient delivery of energy to the discharge light.

20

The reduction in inductor losses and improved current profile result in substantial operational power savings over current ballast implementations.

25 Saturation is a limitation occurring in an inductor. Initially as the current (I) through an inductor is increased the magnetic flux (ϕ) generated by the inductor increases in proportion to it. At some point further increases (dI) in current lead to progressively smaller increases ($d\phi$) in magnetic flux. Saturation occurs substantially at the extreme ends of B vs. H curve of the inductor where $dI/d\phi$ is small or zero (B =magnetic flux density; H =magnetic field intensity).

30

Accordingly, in a first of its aspects, the present invention may provide a method for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a
5 predetermined value of the frequency of said alternating power signal, the method including;

maintaining the value of the frequency of said alternating power signal to be less than said predetermined value.

10

Whereas existing ballast control systems operate at power signal frequencies above resonance, at which the induced voltage generated by the ballast inductor is high, so as to ensure that the power-regulating effect of the ballast
15 inductor is optimal, known as dynamically stable, the present invention, in its first aspect, proposes the converse of this, known as dynamically unstable. Consequently, in controlling an AC power signal to a ballast circuit below the resonance frequency of that
20 circuit the present invention, in its first aspect, is able to operate in a frequency regime in which the induced voltage generated by the ballast inductor is much reduced. Delivery of power to the discharge light is rendered more efficient, however, the power-regulating
25 effect of the ballast inductor is reduced or substantially lost as a consequence. Consequently, the method of power control may provide a power-regulating function by monitoring power delivered to the ballast circuit and/or the discharge light via the ballast
30 circuit, and controlling the AC power signal (e.g. by controlling the inverter that may supply it) according to the power so monitored.

The present invention also preferably includes the making of (and the responding to changes in) instantaneous measurements of various properties of the AC power supply process for controlling the AC power supply. Preferably the method includes monitoring the power delivered to the discharge light by the ballast circuit, and adjusting the alternating power signal in response to variations in the delivered power so as to stabilise the delivered power.

10

The method may include adjusting any one or more of the: frequency, phase, or mark/space ratio, or any other aspect of the inverter AC power signal when adjusting that signal in response to variations in the delivered power. The duration/shape of positive and/or negative polarity portions of individual cycles (e.g. a half-cycle) of the AC power signal may be separately and independently adjusted for this reason.

20 Since the power ultimately delivered to the discharge light via the ballast circuit is dependant upon the frequency response (e.g. resonance profile) of the ballast circuit the method preferably includes varying the (e.g. inverter) AC power signal according to the frequency response of the ballast circuit when responding to variations in the delivered power so as to cause a desired variation/stabilisation in delivered power.

30 Since (e.g. inverter) AC power signal frequency is below resonance, increases in power signal frequency will result in a decrease in power delivered to the discharge light by the ballast circuit. Conversely decreases in frequency result in an increase in such delivered power. Preferably the method includes increasing or decreasing

the frequency of the (e.g. inverter) AC power signal in response to the detection of an undesired increase or decrease respectively in the power delivered to the discharge light via the ballast circuit.

5

The control method means most preferably includes increasing the frequency of (e.g. for individual cycles or half-cycles of) the (e.g. inverter) AC power signal in response to increases in the delivered power, and to
10 reduce the frequency of (e.g. for individual cycles or half-cycles of) the inverter AC power signal in response to decreases in the delivered power, thereby to stabilise the delivered power. The important distinction here is that the AC power signal is always below the natural
15 resonance value of the ballast circuit.

The control method preferably includes maintaining the frequency of the (e.g. inverter) AC power signal at a value sufficiently low that during at least a part of a
20 cycle of the power signal, the inductor means of the ballast circuit is caused to saturate (i.e. passes the extreme end of the inductor B/H curve), whereby the inductor effectively becomes a resistive element only and losses are therefore reduced. This efficiency is achieved
25 by forcing the resonant circuit to allow the remaining (i.e. saturated) part of each half cycle of the AC power signal directly through to the fluorescent light as a substantially steady signal. This will normally cause a rapid increase in the current in the light itself that
30 would lead to the onset of the discharge process entering into the "ark discharge" condition. This would be most disastrous as the ballast for over-current and the light be irreparably damaged. The present invention therefore preferably maintains this delicate balance between

efficient power consumption and decent into destructive the "ark discharge" condition by the application of high speed feedback and predictive forecasting of change. Consequently, by operating in the sub-resonant regime the present invention, in its first aspect, most preferably enables the delivery of a substantially steady current to a discharge light, via a ballast circuit, over a significant but controllably variable proportion of any given cycle or half-cycle of the (e.g. inverter) AC power signal.

Preferably, the control method includes monitoring one or more selected properties of the AC power signal, or a DC signal from which the AC signal may be derived, (e.g. post-inverter circuits) including some or all of the following; voltage input to the inverter circuit where an inverter is used to generate the AC power signal from a DC power signal, voltage and/or current present within the ballast circuit, voltage and/or current delivered to the discharge light, and to derive from the monitored continuous values a measure, estimate or profile of the power delivered to the discharge light.

The selected property of the a.c. power signal may be the electrical voltage and/or current associated with that signal. The voltage/current magnitude, or amplitude, or its instantaneous value(s) may be so monitored.

The selected property is preferably the value of the electrical currents both as present within the ballast circuit and as concurrently delivered to the discharge light.

The power control method may include comparing the values of said electrical currents and/or voltages (either individually, or as combined/summed) present within the ballast circuit and concurrently delivered to the discharge light, to predetermined respective reference values thereof and to derive from such comparison the (e.g. average) measure of the power delivered to the discharge light.

- 10 The predetermined reference values are preferably values of the selected properties which correspond with (and are therefore indicative of) the discharge light operating normally. These predetermined reference values may be stored within a power control means (see below) for
15 access and use as and when required thereby.

The predetermined respective reference values are preferably values corresponding with a predetermined value of power being delivered to the discharge light via
20 the ballast circuit.

The power control method preferably includes sampling values of any of the various (e.g. inverter) AC power signal once within separate successive sampling periods,
25 wherein each sampling period is no greater in duration than the one half of the duration of a single cycle of the AC power signal. Preferably, the sampling occurs once within each half period/cycle of the AC power signal.

- 30 Preferably the power control method includes sampling the current passing through the ballast circuit and/or the discharge light (concurrently) at a time $0.3T$ into a given half-cycle of the (e.g. inverter) AC power signal, where T is the duration of that half cycle. Such sampling

should preferably be performed at a point that is neither too early that it "sees" (i.e. the sample represents) predominantly the energy property in the period where the most change is occurring due to inductor magnetisation and the variable negative resistance effect of the light itself are at there greatest, and not too late that no reference is possible to the reactive effect of the resonance circuit itself. The optimal sampling time has been determined by experiment to be at a point 0.3T into each half cycle.

A consequence of supplying AC power (e.g. inverter operation) well below resonance, as discussed above, is that the electrical current supplied to the discharge light acquires a substantially squarer waveform which results in a substantially more constant light output from the discharge light during those portions of the square waveform in which the supplied current is substantially constant (i.e. during the saturation of the ballast inductor). Furthermore, since the power monitoring and control method described above enables cycle-by-cycle adjustment of the frequency of the inverter AC power signal to the discharge light, the resultant variation in frequencies tends to reduce the overall electromagnetic interference (EMI) produced by the ballast circuit and/or discharge light in use.

The power control method may include maintaining the value of the frequency of the inverter AC power signal to be about 1/2 of the natural resonance frequency of the ballast circuit. This has been found by experimentation to produce the most efficient operation whilst still being able to maintain the ballast outside of the

damaging arc discharge condition, this is achieved by the use of intelligent control circuits.

The present invention, in a second of its aspects, may
5 provide a power controller for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a predetermined value of the frequency of said alternating power signal, including:

10 a power control means arranged to control the AC power signal to maintain the value of the frequency of said AC power signal to be less than said predetermined value.

15 The power control means is preferably arranged to monitor the power delivered to the discharge light by the ballast circuit, and to adjust the AC power signal in response to variations in the delivered power so as to stabilise the delivered power.

20 The power control means preferably includes power monitor means arranged to monitor the value of a selected property of the AC power signal: as input to the ballast circuit; and/or, as present within the ballast circuit;
25 and/or, as delivered to the discharge light, and to derive from the monitored value of the selected property a measure of the power delivered to the discharge light.

Monitoring of the DC power supplied to an inverter for
30 use in generating the AC power signal may also be done by the power monitor.

Preferably, the selected property is the value of the electrical currents and/or voltage both as present within

the ballast circuit and as concurrently delivered to the discharge light. The selected property may be the voltage and/or current.

- 5 The power monitor means is preferably arranged to compare the values of the electrical currents present within the ballast circuit and concurrently delivered to the discharge light, to predetermined respective reference values thereof and to derive from that comparison the
10 measure of the power delivered to the discharge light.

Preferably, the predetermined respective reference values are values corresponding with a predetermined value of power being delivered to the discharge light via the
15 ballast circuit.

The power monitor means is preferable arranged to sample values of the selected property of the AC power signal once within separate successive sampling periods, wherein
20 each sampling period is no greater in duration than the one half of the duration of a single cycle of the AC power signal.

The power control means may be arranged to adjust any one
25 or more of the frequency, amplitude, or phase of the AC power signal when adjusting that signal in response to variations in the delivered power.

The power control means is preferably operable to adjust
30 the AC power signal according to the frequency response of the ballast circuit when responding to variations in the delivered power so as to cause a stabilisation in delivered power.

Preferably, the power control means is arranged to decrease the frequency of the AC power signal in response to decreases in the delivered power, and to increase the frequency of the AC power signal in response to increases
5 in the delivered power, thereby to stabilise the delivered power.

Most preferably the power control means is arranged to maintain the frequency of the AC power signal at a value
10 sufficiently low that during at least a part of a cycle of the AC power signal an inductor means of the ballast circuit is caused to saturate, whereby the inductor becomes substantially only a resistive element of the ballast circuit thereby reducing energy dissipated
15 therein.

The power controller may be arranged to operate in conjunction with an inverter means arranged to receive a direct current (DC) power input signal and to generate
20 the alternating (AC) power signal therefrom for powering the discharge light via a ballast circuit, and the power control means preferably then includes an inverter control means arranged to generate inverter control signals for controlling the inverter so as to control the
25 AC power signal generated thereby.

The power controller may include the power control means and the inverter means.

30 The present invention in its third aspect proposes, at its most general, when supplying start-up AC power to a discharge light via a ballast circuit, controlling the frequency of the AC power signal so as to be sufficiently above the resonance frequency of the ballast circuit that

the discharge light will not strike, and to reduce the signal frequency until it is sufficiently close to the resonant frequency to cause the discharge light to strike. The invention, in its third aspect, is particularly (but not exclusively) suited for use in powering a discharge light which does not have a heater circuit(s) for heating the electron emitter(s) of the light.

Reducing the AC power signal frequency in this way, from a high value to a sufficiently low value, amounts to a search for a value of voltage, delivered by the ballast circuit to the discharge light which is merely sufficient (i.e. just enough) to cause the discharge light to strike. The procedure takes advantage of the gentle voltage ramp associated with the ballast circuit's resonance profile at frequencies above resonant frequency. The ramp is such that the voltage across the ballast circuit, and therefore the voltage delivered across the discharge light, increases gently as the AC power signal frequency decreases towards the resonant value.

Accordingly, in a third of its aspects, the present invention may provide a method for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a predetermined value of the frequency of said alternating power signal, the method including;

controlling the frequency of the AC power signal to be greater than the predetermined value by an amount sufficient to prevent operation of the discharge light, and to subsequently reduce the frequency of the AC power signal until the discharge light becomes operational.

Consequently, rather than switching on a discharge light simply by applying a very large strike voltage thereto, being a voltage which is more than sufficient to cause
5 the light to operate, the present invention proposes searching for a strike voltage which is merely sufficient to cause the light to operate. Clearly, this is more energy efficient. Furthermore, in gently raising the voltage output to the ballast circuit, and ultimately
10 delivered to the discharge light, one reduces the stresses that are inevitably applied to the ballast and discharge light components when applying sharply rising high-voltage strikes as is presently done in the art.

15 The control method may include reducing the frequency of the inverter output signal continuously thereby sweeping through successively lower frequency values, or searching in a step-wise fashion in which the AC power signal frequency acquires a succession of separate successively
20 lower values spaced in frequency. The spacing between successive such frequency values (i.e. the search step size) may be fixed or variable. Consequently, the actual resonance frequency of the ballast circuit is searched for when switching on the discharge light, that is to
25 say, the frequency at which the ballast circuit resonates in its current condition.

Obviously, ballast circuit components, especially capacitors thereof, are subject to considerable variation
30 in their capacitance during the period of time (years) a given discharge light will typically be used. Of course, changes in the value of such capacitance will change the value of the AC power signal frequency at which the ballast circuit resonates and therefore the resonance

profile of the ballast circuit as a whole. Consequently, the value of AC power signal frequency sufficient to cause the ballast to deliver a voltage to a discharge light sufficient to cause the light to become operational will also tend to vary over time. Indeed, in prior art systems, where a given fixed start-up power signal frequency may have been selected initially as being sufficiently high to generate the required strike voltage at the light, a subsequent increase in the resonant frequency of the ballast circuit may render that start-up frequency so close to resonance (or even at resonance) that the strike voltage generated by the ballast circuit operating at the start-up frequency damages the ballast and may destroy the discharge light.

15

The above frequency searching technique inherently accounts for such variations in ballast circuit resonance frequency and provides a safety mechanism which avoids such inadvertently excessive strike voltages.

20

The power control method preferably includes monitoring the value of a selected property of the AC power signal: as input to the ballast circuit and/or as present within the ballast circuit; and/or as delivered to the discharge light, and halting reduction in the frequency of the AC power signal when the value of the selected property reach maximum predetermined values or a change of operating state is detected.

25

For example, the detection of the presence of, or a rapid rise in, current through the discharge light is indicative of the onset of a plasma discharge state and therefore of the light becoming operational.

30

- This monitoring function is also beneficial in another possible condition of operation: that of ballast turn-on with a faulty or missing target discharge light. When no light is fitted to the ballast and a user tries to switch
5 on a light by supplying power to the ballast, the only load is the ballast resonator. As it is preferable to operate close to resonance frequency to achieve an induced voltage high enough to strike the discharge light the current, at close to resonance frequency, is very
10 high and the stresses on components cannot be sustained for long. Normally the light would strike and the stresses would decrease but with a missing or faulty light this would not happen. However using the present aspect of the invention, this condition may be detected
15 as the lack of a reduction in load before maximum power is measured to have been reached. Upon detection of this condition the inverter can be safely shut down without damage.
- 20 To achieve detection of faulty or dangerous light discharge conditions, the value of the current through and/or voltage across the light is measured as the (e.g. inverter) AC power signal frequency is reduced. If any one or more of these values pass predetermined maximum
25 values before a marked power reduction is read (NB: the strike condition causes a sudden reduction in power through the resonator path) then the fault condition can be declared.
- 30 For example, in order to prevent the frequency of the (e.g. inverter) AC power signal from approaching the resonance frequency value too closely while being reduced, with the resultant risk of damage to the ballast circuit and/or discharge light components, the power

control method preferably includes monitoring of the current and/or voltage applied to the ballast circuit and/or the discharge light and halting power signal frequency reductions when the monitored voltage/current is deemed to be too high. This monitoring function protects the ballast circuit and discharge light from damage through excessive signal levels when a fault condition exists in the discharge light, or when no discharge light is actually present (unknown to the user).

The power control method may include halting such further reduction in the frequency of the a.c. power signal as discussed above when the value of the selected property either: is detected to have reached a predetermined threshold value (e.g. indicating a fault condition); or, is detected to have reached a value indicative of the discharge light being operational, whichever occurs first.

Most preferably, the power control method is arranged for use in powering a discharge light which does not have a heater circuit(s) for heating the electron emitter(s) of the light.

Consequently, the power control method preferably includes controlling the inverter AC power signal to generate an alternating power signal intended solely for generating a sufficient voltage across the discharge light to cause it to operate, but which is not (or need not) be sufficient for heating the electron emitter(s) of the light which may or may not be present. A clear energy efficiency.

The power control method preferably includes the use of a processor means, such as a microprocessor, for processing software arranged to generate control signals for use in controlling the inverter AC power signal.

5

In a sixth of its aspects, the present invention may provide a power controller for controlling the power delivered to a discharge light by an alternating (a.c.) power signal via a ballast circuit which resonates at a
10 predetermined value of the frequency of said alternating power signal, including:

a power control means arranged to control the frequency of said a.c. power signal to be greater than the predetermined value by an amount sufficient to prevent
15 operation of the discharge light, and to subsequently reduce the frequency of the a.c. power signal until the discharge light becomes operational.

Preferably, the power control means is operable to reduce
20 the frequency of the a.c. power signal continuously thereby sweeping through successively lower frequency values.

The power control means is preferably operable to monitor
25 the value of a selected property of the a.c. power signal either: as input to the ballast circuit; and/or as present within the ballast circuit; and/or as delivered to the discharge light, and to halt reduction in the frequency of the a.c. power signal when the value of the
30 selected property is detected to have reached a value indicative of the discharge light being operational.

The power control means may be operable to monitor the value of a selected property of the a.c. power signal

generated either: as input to the ballast circuit; or as present within the ballast circuit; or as delivered to the discharge light, and to halt reduction in the frequency of the a.c. power signal when the value of the selected property is detected to have reached a predetermined threshold value or a change of operating state is detected.

The power control means may be operable to halt reduction in the frequency of the a.c. power signal when the value of the selected property either: is detected to have reached said predetermined threshold value; or, is detected to have reached said value indicative of the discharge light being operational, whichever occurs first.

The power control means preferably includes a processor means for processing software arranged, when processed, to generate control signals for use in controlling the a.c. power signal.

The power controller may be arranged to operate in conjunction with an inverter means arranged to receive a d.c. power input signal and to generate the alternating (a.c.) power signal therefrom for powering the discharge light via a ballast circuit, and the power control means preferably then includes an inverter control means arranged to generate inverter control signals for controlling the inverter so as to control the a.c. power signal generated thereby.

The power controller may include the power control means and the inverter means.

The present invention in its fifth aspect proposes, at its most general, when delivering an alternating power signal to a discharge light via a ballast circuit, adjusting the form of the alternating power signal in response to changes in the power which occur within multiples of half-cycles thereof, the adjustments being made such that the ballast circuit delivers the desired power to the discharge light.

10 In a fifth of its aspects the present invention may provide a method for controlling the power delivered to a discharge light from a source of direct-current (DC) power, the power being delivered via a signal inverter and subsequent ballast circuit as an alternating (AC) power signal, the method including:

15 monitoring variations in the DC power input to the signal inverter, and varying the frequency of the alternating power signal according to detected variations in the DC power input, thereby to control variations in the power supplied to the discharge light via the ballast circuit.

20 Preferably the control method includes varying the frequency of the AC power signal so as to minimise variations in the power supplied (e.g. the true power) to the discharge light via the ballast circuit.

25 Variations in the frequency of the alternating output signal are most preferably made according to the signal response of the ballast circuit via which the alternating power signal is delivered to the light.

30 Most preferably, the invention in this aspect includes maintaining the AC power signal (e.g. inverter) frequency

below the resonance frequency of the ballast circuit. Most preferably, the invention in this aspect includes controlling the AC power delivered to the discharge light according to the first (and any other) aspect of the
5 invention.

The ballast circuit preferably has a signal response which resonates at a predetermined frequency of the AC power signal, and the method preferably includes varying
10 the frequency of the AC power signal: to approach the resonance frequency when the DC power input is determined to have risen; and, to recede (e.g. as determined by operation at below resonant the frequency of the ballast circuit) from the resonance frequency when the DC power
15 input is determined to have fallen.

The control method preferably includes determining an average value of the DC power input to the inverter over a predetermined averaging period, and to vary the
20 frequency of the AC power signal according to a difference value being the difference between an instantaneous value of the DC power input and the average value thereof.

25 The control method preferably includes determining for example the fundamental oscillation period (e.g. main lowest frequency component) of the variations in the DC power input, whereby the predetermined averaging period is of a duration substantially equal to the fundamental
30 oscillation period of the variations. The inverter control means may be arranged to determine temporal position of the lowest value (e.g. trough) of the DC power input during the oscillation period thereof, and to

commence the predetermined averaging period at the temporal position so determined.

5 Preferably, the difference value is determined immediately prior to commencement of the generation of a given cycle of the AC power signal, and the control method preferably includes modifying the e.g. base frequency of the given cycle AC power signal according to the difference value.

10

The control method may include predicting a future difference value e.g. from a plurality of separate and/or a successive sequence of difference values. This method is referred to as predictive AC compensation herein and
15 may be an independent aspect of the present invention.

A correction (change) in inverter AC power signal frequency will not immediately cause a change in power delivered to the ballast circuit and/or discharge light.
20 The correction will appear to be ineffective and may prompt further corrections. This lag is caused by the resonant elements changing their reactance values only after several complete AC power signal cycles have occurred.

25

The power controller may be arranged to operate according to this method being arranged to receive a signal corresponding to the instantaneous value of the DC power supplied to the AC inverter. The use of this signal can
30 then modify the shape and period of the inverter AC drive signal(s). The power controller may include the power control means and the inverter means.

One example of this method exploits the fact that there is always an element, even if very small, of the external mains supply AC component (50/60Hz) within the DC power supplied to the inverter. The method preferably includes
5 reading/sampling this signal and synchronising sampling periods to that period of the AC component within the DC signal supplied to the inverter (10ms for 50Hz, 8.33ms for 60Hz). The method preferably then includes taking multiple samples of the values of the inverter AC power
10 output signal properties (e.g. current values and/or voltage values) for each period of the AC power output signal and storing those samples as references. An average of the total samples/readings taken within a whole AC period is preferably then calculated for use as
15 a temporal mean reference for the next AC period of the inverter output.

In the next AC inverter output period, the signed difference between an individual recorded sample of the
20 previous period and the mean reference is used to compensate an individual sample in the current AC period. This difference is then used to calculate the value by which the frequency of the inverter AC power supply should be compensated to achieve the closest flat power
25 response in the delivered light power for changing input DC values. This temporal sampling shift means that the effect of inverter AC frequency and mark/space ratio changes can be seen in context of their special position in each successive source AC period. This eliminates lag
30 effects and still allows for the necessary cycle-by-cycle corrections.

In a simple example, in order to apply a correction to, say, the 30th sample in a given current period, it would

be desirable to apply that correction at an earlier time (at the 20th sample of that period), because the correction takes a finite time to come into effect. However, it is clearly impossible to do that, because at
5 the time of the 20th sample, the controller cannot know what the value of the 30th sample will be, as it occurs later. Hence the controller uses the value (or difference value) of an earlier sample (e.g. the 30th sample of the previous period) as a prediction of what
10 the 30th sample will be in the current period, and makes the correction on that basis.

More generally, this method encompasses adjusting the frequency of the power output signal based upon
15 measurement(s) of deviation of voltage and/or current from a desired value taken at an earlier time.

Preferably, the adjustments relating to each portion or value of a given AC cycle is based on an earlier (e.g.
20 the equivalent) portion of an earlier cycle. More preferably, the adjustment is applied in advance of the portion or value to be corrected.

In a sixth of its aspects, the present invention may
25 provide a power controller for controlling the power delivered to a discharge light from a source of direct-current (DC) power, the power being delivered via a signal inverter and subsequent ballast circuit as an alternating (AC) power signal, the power controller
30 including:

control means arranged to monitor variations in the DC power input to the inverter means, and to vary the frequency of the alternating power signal according to detected variations in the DC power input, thereby to

control variations in the power supplied to the discharge light via the ballast circuit.

5 The control means is preferably arranged to vary the frequency of the AC power signal so as to minimise variations in the power supplied to the discharge light via the ballast circuit.

10 The ballast circuit preferably resonates at a predetermined frequency of the AC power signal, and the inverter control means is preferably arranged to vary the frequency of the AC power signal: to approach the resonance frequency when the DC power input is determined to have risen; and, to recede from the resonance
15 frequency when the DC power input is determined to have fallen.

The control means may be arranged to determine an average value of the DC power input to the inverter over a
20 predetermined averaging period, and to vary the frequency of the AC power signal according to a difference value being the difference between an instantaneous value of the DC power input and the average value thereof.

25 The control means is preferably arranged to determine the oscillation period (preferably the fundamental period) of the variations in the DC power input, whereby the predetermined averaging period is of a duration substantially equal to the aforesaid oscillation period.

30

The difference value is preferably determined immediately prior to commencement of the generation of a given cycle of the AC power signal, and the control means is preferably arranged to modify the frequency (e.g. base

frequency) of the given cycle according to the difference value immediately prior to the generation of the given cycle.

5 The present invention in its seventh aspect, at its most general, proposes controlling the radiant power output of the light by adjusting the power in an alternating output signal delivered to the light via a ballast circuit to levels below that at which operation of the light would
10 cease. By injecting appropriately timed and shaped excitation pulses into the signal delivered to the light via the ballast circuit the light is given sufficient power to remain operational. This provides a sensitive light dimming function and control.

15 It is currently known that a degree of dimming in electronic, type 'A', ballasts is possible and this is performed by way of varying the peak energy supplied by the ballast inductor by way of either reducing its input
20 DC supply voltage or changing the frequency of the inverter AC signals to increasing values above resonant which has the effect of lowering the average voltage seen by the discharge light. Both these methods fail to deliver good dimming range and efficient power saving
25 proportional to reduction in radiant light output. The present invention in its following aspect creates a technique that aims to overcome this weakness.

Accordingly, in an seventh of its aspects, the present
30 invention may provide a method for controlling the AC power signal supplied to a discharge light via a ballast circuit containing an inductor, including:

inputting an excitation pulse signal to the discharge light via the ballast circuit having a

frequency which is equal to, or a multiple of, the resonant frequency of the ballast circuit.

- The method preferably includes monitoring of the voltage generated across the inductor in response to the AC power signal, and determining the phase of that voltage. Consequently, pulse excitation may be input in synchrony with the phase of the inductor voltage.
- 10 Preferably, the excitation pulse signal is input to the discharge light only when the inductor voltage is substantially at or is close to zero (e.g. the inductor is at or close to a zero energy state). At this state the new pulse injection will not have to absorb any
- 15 demagnetising energy from the inductor. This will naturally induce a single cycle that is power efficient and allows the LC ballast circuit to use the full pulse period to generate gain. This means that the voltage so generated across the capacitor the LC ballast circuit is
- 20 maximised. This is delivered substantially as the discharge light will begin to experience a gradual collapse in its plasma, as the average energy delivered to it is reduced. This has been found to increase the voltage required to be applied across the light to
- 25 maintain any discharge at the lower average energy. This effect has been found by the inventors to increase the voltage required to maintain the discharge to as much as twice the full energy level.
- 30 It is this need for greater excitation voltages during gradual reduction in average energy that sets the limit of dimming possible. The voltages become too great to be safe for the cables that connect the light to the ballast. Also the extreme voltage will have an adverse

effect on the electron emitter material of the light electrodes, causing them to be pitted and their surfaces to be vapourised. This has been found to limit the safe dimming zone to approximately 75% of the maximum.

5

It is also documented that electrode heating is required in prior art methods to achieve dimming. This is not the case for the current invention, indeed the addition of independent heating to the electrodes tends to cause a
10 reduction in the range of the dimming possible.

An important feature of this aspect of the invention is the power saving for radiated light output reductions. This means that with the current invention a fluorescent
15 tube dimming to 50% radiate light output may save 50% of the load seen by the mains supply input. This is a very desirable effect as dimming can now become part of an overall power saving strategy.

20 In a eighth of its aspects, the present invention may provide a power controller for controlling the a.c. power signal supplied to a discharge light from an a.c. power source via a ballast circuit containing an inductor, the power controller including:

25 control means arranged to cause the a.c. power source to generate an excitation pulse signal for input to the discharge light via the ballast circuit having a frequency which is equal to or a multiple of the resonant frequency of the ballast circuit.

30

The controller means is preferably arranged to monitor the inductor voltage generated across the inductor in response to the a.c. power signal, and to determine the phase of that voltage.

Preferably, excitation pulse injection occurs when the magnitude of the inductor voltage falls below a predetermined threshold value. This corresponds to substantially zero-inductor-energy state.

5

The ballast circuit preferably resonates at a predetermined frequency of the a.c. power signal, wherein the excitation pulse signal is generated to have a frequency being substantially equal in value to (or any multiple of) the resonance frequency.

10

In a ninth of its aspects, the present invention provides a method for controlling the power delivered to a discharge light in use by an alternating (AC) power signal via a ballast circuit, the method including;

15

monitoring the ambient illumination level in the vicinity of the light, and adjusting the frequency of said AC power signal to adjust the power delivered to, and ultimately radiated by, the light thereby to control the ambient illumination level. Preferably, the control is such as to maintain the ambient illumination level at a substantially constant value.

20

Preferably the ballast contains a resonant circuit element that is used to control the average power delivered to the discharge light. The power may be reduced using any scheme including; source DC level reduction, mark/space ratio reduction, inverter frequency increase or resonant cycle skipping. It may also be that several of these techniques are employed together or in sequence. The current invention uses both frequency reduction and resonant cycle skipping to achieve the best dimming range.

30

The method may include reversibly adjusting the (e.g. average) power delivered to the discharge light in predetermined steps or in a fully variable slope (e.g. continuously). This method may also include reversible
5 power adjustment to a final level in which all possible stable reduction in radiated light by reduction in average power has been performed, thereby to stop all AC power being input to the lights (e.g. stop all inverter activity) and so reduce the power radiated by the light
10 to zero.

To avoid the problem of over compensation for ambient light changes, such as when part of the light source is temporarily obscured by a momentary object, schemes for
15 ignoring sudden changes may need to be employed. In the current aspect of the invention, this is preferably achieved by the method of reading fixed temporally spaced instantaneous ambient illumination level samples (e.g. via a suitable analog to digital converter) and employing
20 a constant averaging technique.

This technique is adding each new such samples into a data storage device (e.g. a large digital accumulator), after each value is added a predetermined multiple of the
25 maximum size any sample is subtracted from the whole data storage device (accumulator). By way of example; if the maximum size of the accumulator is 100,000 and the maximum size of any particular sample is 100, the accumulator is 1,000 times larger than a single sample.
30 So every time a new sample is added a value of 1,000th of the current accumulator current is subtracted, in this way a constant average is maintained. The average sample value being the accumulator size divided by 1,000. So by

increasing the multiple size of the accumulator the period of average is increase and vice versa.

In a tenth of its aspects, the present invention provides
5 a power controller for controlling the power delivered to a discharge light in use by an alternating (AC) power signal via a ballast circuit, the controller including;

Control means arranged to monitor the ambient illumination level in the vicinity of the light, and
10 change the AC power signal to adjust the power delivered to, and ultimately radiated by, the light thereby to control the ambient illumination level. Preferably, the control is such as to maintain the ambient illumination level at a substantially constant value.

15

Preferably the ballast contains a resonant circuit element that is controlled by the power controller and therefore able to control the average power delivered to the discharge light. The power may be reduced using any
20 scheme including; source DC level reduction, mark/space ratio reduction, inverter frequency increase or resonant cycle skipping. It may also be that several of these techniques are employed together or in sequence. The current aspect of the invention preferably uses both
25 frequency reduction and resonant cycle skipping to achieve the best dimming range.

The control means is preferably arranged to reversibly adjust the (e.g. average) power delivered to the
30 discharge light in predetermined steps or in a fully variable (e.g. continuous) slope. This may also include reversible adjustment to a final level in which all possible stable reduction in radiated light by reduction in average power has been performed, thereby to stop all

AC power input to the discharge light and so reduce the power radiated by the light to zero.

In a eleventh of its aspects, the present invention may
5 provide a method for controlling the power delivered to an discharge light by an alternating (AC) power signal via a ballast circuit, the method including;

providing a re-programmable control means operable to process software arranged, when processed, to generate
10 control signals for use in controlling the (e.g. inverter) AC power signal to adjust the power delivered to the discharge light.

The method preferably includes monitoring predetermined
15 conditions in the environment of the discharge light, and to re-program the control means according to the conditions whereby to modify said software which, when processed by the control means, generates accordingly modified control signals for use in controlling the (e.g.
20 inverter) AC power signal.

The method may include re-programming according to a predetermined re-program signal upon receipt of which the control means modifies the software which, when processed
25 thereby, generates accordingly modified control signals for use in controlling the (e.g. inverter) AC power signal.

Preferably re-programming is controlled via a remote re-
30 program signal, preferably wirelessly. Preferably the method includes re-programming in response to changes in the predetermined conditions.

Preferably, predetermined conditions include one or more of: a property of said (e.g. inverter) AC power signal; the ambient illumination level at location of the discharge light; the presence within the environment of the discharge light of other the power control means associated with other discharge lights.

The control method may control the power delivered to a plurality of discharge lights each of which is separately controlled by a respective separate re-programmable control means discussed above wherein the separate control means are controlled collectively.

The collective control of a given one of the plurality of discharge lights may include monitoring the operating conditions of the control means of each of the other discharge lights, and re-programming the given control means according to the monitored operating conditions whereby the given control means modifies the software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal delivered to the given discharge light.

Preferably, any given one of said separate control means is operable to monitor the operating conditions of each of the other of said separate control means, and to re-program according to said monitored operating conditions whereby the given control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the inverter AC power signal delivered to the discharge light associated with the given control means.

In a twelfth of its aspects, the present invention may provide a control apparatus for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit, the apparatus
5 including;

a re-programmable control means operable to process software arranged, when processed, to generate control signals for use in controlling the AC power signal to adjust the power delivered to the discharge light.
10

The re-programmable control means is preferably operable to monitor predetermined conditions in the environment of the discharge light, and to re-program according to the conditions whereby the control means modifies the
15 software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

Preferably, the re-programmable control means is operable
20 to re-program according to a predetermined re-program signal upon receipt of which the control means modifies the software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

25 The control means is preferably arranged to receive a remote re-program signal, preferably wirelessly. The power control means is preferably operable to re-program in response to changes in the aforesaid predetermined
30 conditions.

The predetermined conditions may include one or more of: a property of said a.c. power signal; the ambient illumination level at location of the discharge light;

the presence within the environment of said discharge light of other said power control means associated with other discharge lights.

5 Apparatus may be provided for controlling the power delivered to a plurality of discharge lights each of which is separately controlled by a respective separate re-programmable control means as discussed above wherein
10 separate control means are arranged to operate collectively.

Preferably, any given one of said separate control means is operable to monitor the operating conditions of each of the other of said separate control means, and to re-
15 program according to said monitored operating conditions whereby the given control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal delivered to the discharge light associated
20 with the given control means.

In a thirteenth of its aspects, the present invention may provide a communications apparatus for connecting multiple ballast devices together, the apparatus
25 including;

a re-programmable control means operable to process software which, when processed, generates control commands and control protocols for controlling the multiple ballast devices. An electrically isolated low
30 voltage communications interface is preferably included in the apparatus that preferably operates using a single bi-directional data signal to minimise the number of wiring connections required between individual ballast devices. A software communications protocol that allows

individual lights to be connected to the communications apparatus and preferably to cause the multiple ballasts to operate collectively (and preferably automatically) to form a single coherent array of radiant light energy.

5

The re-programmable control means is preferably operable to monitor predetermined conditions near or associated to the light array, and to re-program the individual members of the array according to the ambient needs or manual requirements. When adjusted automatically the array may be instructed by the automatic nomination of a single member that acts as the master controller, this master informs the slaved members as to the required total energy requirement to maintain the average illumination required. The control means can also be responsive to remote control means that can override this automatic process and force a predefined illuminations state.

A further feature of this aspect of the invention is the ability for individual or arrays to inform remotely connected logging devices as to their current power consumption levels and maintenance states. This means that the instantaneous power consumption of any installation is preferably able to be read by a remote monitoring station. This means that the power usage can be determined and recorded so as to accurately declare the cost of operating a lighting strategy and even lighting control management schemes changed to maximise power savings and energy usage. This is very important in the efforts to save national CO² emissions.

The invention in any one of its aspects may be employed together with, or in combination with, the invention in any one or more of the other of those aspects.

In a further of its aspect, the present invention may provide a method as described above. In yet a further of its aspects, the present invention may provide a power
5 controller, a ballast circuit, and/or control apparatus as described above.

Examples of the invention shall now be illustrated with reference to the accompanying drawings in which:

10 Figure 1 schematically illustrates a typical frequency response for an LC-resonant circuit displaying a resonance profile centred upon a specific signal resonance frequency;

 Figure 2 schematically illustrates the signal
15 response of an LC-resonant ballast circuit;

 Figure 3 illustrates schematically a signal inverter means, inverter control unit, ballast circuit and discharge light arranged in use;

 Figure 4 schematically illustrates the inverter unit
20 ballast circuit and discharge light of Figure 3, together with the monitor means of the control unit of Figure 3;

 Figure 5 schematically illustrates excitation pulses and ballast inductor voltage zero crossings;

 Figure 6 schematically illustrates the waveform of
25 electrical current passing through a ballast inductor as it reaches and passes through saturation thereof;

 Figure 7 illustrates supply voltage, supply current and radiate light output plots of fluorescent discharge lights;

30 Figure 8 illustrates a power controller and signal inverter controlled by the power controller;

 Figure 9 illustrates examples of power controller control output signals as generated by the power

controller of Figure 8, and the resultant signal inverter output signals of the signal inverter controlled thereby;

Figure 10 illustrates the form and relative timings of periodic variations in the d.c. power input to a signal inverter from which the inverter generates an a.c. power signal, and the variation in frequency of that a.c. power signal according to the rising and falling of the varying d.c. power input;

Figure 11 illustrates schematically a signal inverter means, inverter control unit, ballast circuit and discharge light arranged in use.

Figure 1 schematically illustrates the frequency response of a typical series LC-resonant circuit, such as a ballast circuit. Such a circuit includes an inductor of inductance L connected in series electrical connection with a capacitor of capacitance C . Such a circuit will, in practice, typically also contain an electrical resistance R caused by components (e.g. wires) of the circuit, particularly the inductor.

It is well known that the total impedance Z of such a resonant circuit is simply the sum of the individual impedances of the resistive, inductive and capacitive components of the circuit. The resistive component is purely ohmic and therefore real, while the inductive and capacitive components are in fact reactive and imaginary. The phase of the inductive reactance leads the phase of the capacitive reactance by 180° in the complex plane. While the magnitude of the resistive component of the impedance is independent of the frequency of an electrical signal passing through the LC-resonant circuit, both the inductive and capacitive reactances are

sensitively dependent upon such frequency. At low frequency values the capacitive impedance component dominates the total impedance of the circuit while at high frequency values the inductive impedance component dominates.

Figure 1 illustrates this relationship in terms of the voltages generated across the capacitive and inductive impedance components of a typical series LC-resonant circuit. When the signal frequency ω is low (region A of Figure 1) the rate of change of the current I passing through the inductor L is low, and consequently the induced voltage V_L where: $(V_L = LdI/dt)$ is correspondingly low and the slowly varying current causes the voltage across the capacitor C of the circuit to be relatively large and dominant. As the signal frequency ω increases so too does the rate of change of the current I passing through the inductor L and, consequently, the induced voltage V_L increases, as does the voltage V_C across the capacitor C . These voltages continue to increase as the signal frequency ω approaches a resonant value ω_{res} at which the voltages V_C and V_L across the capacitor and inductor respectively reach a maximum value. The current I passing through the circuit also reaches a maximum value. The LC-resonant circuit resonates at this point. It is important to note that the inductor generates highly increasing voltages as the resonance area is passed in response to the increasing rate of change of the current this increased voltage is many times greater than the DC supply value is to power the AC inverter. It is this principle that allows the high strike voltage to be achieved but is also the reason for the danger of overload in the inverter as the rate of change current reaches the limit that can be safely sourced by the

inverter electronics. In practice the inverter output frequency does not pass through the resonance value as this the load would destroy the inverter.

5 The high frequency regime, denoted region B in Figure 1, is entered when the signal frequency ω exceeds the resonance frequency. When this occurs, while both the inductor and capacitor voltages, V_L and V_C respectively, begin to decrease with increasing signal frequency, the
10 voltage V_C across the capacitor increases more rapidly than voltage V_L across the inductor. Consequently, in the high-frequency regime the induced voltage generated across the inductor L dominates the voltage across the LC-resonant circuit.

15

Figure 3 schematically illustrates a power controller operatively connected to a discharge light via a ballast circuit in use. Note here that in the present invention the light heaters are not used but are tied together.

20

A signal inverter circuit 7 is arranged to receive a DC power input signal 6 and to generate an alternating (AC) power output signal 8 therefrom for powering the discharge light 13 via the ballast circuit 11. The
25 inverter circuit 7 includes a "high-side" signal generator circuit 9 arranged to generate the positive polarity portions of the alternating output signal 8 of the inverter, and a separate "low-side" signal generator 10 arranged to generate the negative polarity portions of the alternating output signal 8 of the inverter 7.
30

The form and structure of the inverter circuit 7, and its constituent "high-side" and "low-side" portions (9 and 10) may be of a type readily apparent to the skilled

person and shall not be discussed in detail herein. Suffice to say that any suitable form of switching circuitry may be employed in order to alternately switch the polarity of the DC signal 6 input to the inverter circuit 7 before that signal is subsequently output from the inverter circuit. Each of the "low-side" and "high-side" circuits may comprise an appropriately arranged transistor as is illustrated in Figure 4.

10 A ballast circuit 11 is arranged to receive the AC power signal 8 generated by an output from the inverter circuit 7 and to deliver power conveyed by the AC power signal to the discharge light 13 via power terminals, 12 and 14, of the discharge light. The power terminals of the discharge
15 individually deliver current to and from the electron emitter electrodes of the discharge light in use.

The form and structure of the ballast circuit 11 of Figure 3 may be such as would be readily apparent to the
20 skilled person. The present embodiment uses a half bridge approach with a low impedance DC blocked floating return.

A power controller includes an inverter control means 17 and a power monitor means 15 operatively connected to, and in communication with the inverter control means 17
25 via a communications link 16. The inverter control unit 17 comprises a microprocessor control unit (MPU) operatively connected to and in communication with the inverter circuit 7 via a control communications link 18.

30

The power monitor means 15 is arranged to monitor the value of a selected property of the AC power signal 8 generated by the inverter means either/both as present within the ballast circuit 11 or/and as concurrently

delivered to the discharge light 13. The power monitor 15 samples the selected property in question on every half-cycle of the inverter and delivers the sample results to the MPU control unit 17 via the communication link 16
5 between the power monitor and the MPU control unit. In response to the monitored values so received, the MPU control unit controls the inverter circuit 7 so as to maintain the value of the frequency of the AC output signal generated thereby so as to be below the resonance
10 frequency value of the ballast circuit 11 when the discharge light 13 is operating (i.e. has already struck and is conducting).

Control signals generated by the MPU control unit 17 are
15 communicated to the inverter circuit 7 via the communications link 18 connecting the former to the latter. Furthermore, the MPU control unit 17 is arranged to generate control signals for controlling the inverter circuit to adjust the frequency of the AC output signal
20 generated thereby, these adjustments being made in response to variations in the power delivered to the discharge light so as to stabilise that delivered power as follows.

25 The electrical current generated by the inverter means both as present within the ballast circuit 11 and as concurrently delivered to the discharge light 13 is simultaneously sampled by the power monitor unit 15 once within each half-cycle of the alternating waveform of the
30 AC power signal. The sampled values are communicated by the power monitor unit 15 to the MPU control unit 17 via the communications link 16 between the two. The MPU control unit compares the sampled values with pre-stored values of ballast current and concurrent discharge light

current which are known to correspond to the "normal" or acceptable/desirable operation of the particular ballast circuit and discharge light in use. If this comparison indicates that the power delivered to the discharge light exceeds the desired/"normal" value, the MPU control unit generates inverter control signals which cause the inverter circuit 7 to increase the frequency towards the resonant value of the AC power signal generated thereby. Conversely, should the comparison undertaken within the MPU control unit indicate that the power delivered to the discharge light 13 is less than the desired/"normal" value, then the MPU control unit generates inverter control signals which cause the inverter circuit 7 to decrease the frequency away from the resonant value of the AC power signal generated thereby. The aforementioned control signals are communicated to the inverter circuit 7 via the communication link 18 connecting the MPU control unit to the inverter circuit.

Of course, the MPU control unit is operable to vary the AC power signal generated by the inverter circuit according to the frequency response of the ballast circuit when responding to the variations in the delivered power as discussed above. The power-stabilising effect of these variations can be understood with reference to Figure 1.

The behaviour of a fluorescent light when driven, by a DC current, is generally linear but has the strange property of negative resistance that is to say that as power increases, the effective load resistance decreases until the 3rd state of discharge is entered that of "ark discharge". The ark condition is terminal for a fluorescent light and must therefore be avoided.

It has been found that the negative resistance slope (i.e. rate of change of load resistance with respect to power changes) changes as a function of time. All current ballast design techniques employ the same "sine" current drive as they all use a standard LC ballast circuit run at close to the resonant frequency to achieve the best stability of radiated light energy. However if the power profile is altered towards a leading sloped square wave, as per a saturating inductor, the result is different. Initially the current remains the same in the latter part of the half period but at a certain point it will suddenly rise rapidly as the plasma suddenly tries to enter the "ark discharge" phase of discharge. Just before this occurs the radiated power output of the light is increasing in a very efficient zone without a proportional increase in energy consumed. It is the task of the controller MPU to best judge this phase so as to exploit the efficiency but to avoid the onset of the ark discharge.

Thus the invention in its first aspect and in this embodiment operates at below resonant frequency to allow the current profile to exploit this effect. It also means that the apparent frequency-to-radiated energy relationship is reversed. If the inverter AC drive frequency is shifted towards the resonance value the amplitude of the output signal does increase but the energy is merely focused about the centre of the half-cycle. If the frequency is lowered, instead of the expected lowering of energy due to operation further away from resonance it actually increases due to the fact that the inductor is saturated for longer and so the current

profile, described above, is shifted towards the arc discharge event.

So, therefore, the energy in the light increases, as the
5 frequency is shifted further below the resonant value,
and decreases as it is moved closer to it. As the
frequency is steadily decreased, however, it becomes more
and more difficult to maintain control over the safe
point, this sets the extreme limit for operation within
10 this effect. The present invention preferably uses all
the above described techniques to get as close to the
maximum deviation, it preferably does this by trying to
produce the best energy stability that is practically
possible.

15

Referring back to Figure 1, the inverter control unit
causes the signal inverter circuit 7 to operate in the
low-frequency regime (regime A of Figure 1) in which
signal frequencies are below the resonance frequency of
20 the ballast circuit in use. Consequently, increases in
the power delivered to the discharge light from the
inverter circuit via the ballast circuit may be provided
simply by decreasing the AC power signal frequency to
cause that frequency to approach the resonance frequency
25 of the ballast circuit and therefore to "climb" the
resonance peak associated with the frequency response of
that circuit. Conversely, reducing the a.c. power signal
frequency causes the signal frequency to "climb down" the
resonance peak thereby increasing the power delivered to
30 the discharge light.

Since the frequency of the AC power signal supplied to
the inductor of the ballast circuit 11 is low (and
particularly because it is below the resonance frequency

associated with the ballast circuit), the inductor will be caused to saturate during a portion of each half-cycle of the alternating current supplied thereto by the inverter circuit.

5

Figure 6 schematically illustrates an example of an AC waveform of a current I_L supplied to the ballast inductor L by the inverter circuit 7, together with a waveform of the induced voltage V_L generated across the inductor L as a result of the waveform of the current I_L . In the absence of the generation of induced voltage within the inductor L of the ballast circuit 11, an alternating square-wave electrical current waveform 60 as generated by the inverter circuit 7 could, in principle, be delivered to the inductor L . However, due to the rapid variation in supplied current at the falling and rising edges of the square wave current 60, an induced voltage V_L is generated in direct proportion to that rate of current change. As is well known, the induced voltage opposes the change in current responsible for its own creation with the result that an otherwise sharp/step increase in current is reduced to a waveform 61 which increases exponentially at positive polarity portions of the waveform, and decreases exponentially at negative polarity portions thereof. The initially rapid exponential increase/decrease of the rising/falling edge of the waveform 61 of the delivered current I_L is accompanied by a sharp induced voltage spike 70 which subsequently exponentially decays as the delivered current I_L approaches and reaches its maximum steady-state or "saturation" value, and therefore the magnitude of the induced voltage (V_L) is negligible.

Thus, in the low frequency regime, below resonance frequency, one is able to drive the ballast circuit with

the inductor in a saturated state during a portion T_s of each half-cycle period T of the inverter AC current waveform. During this saturation period a substantially constant current is supplied to the discharge light with the beneficial consequence that the light output of the discharged light will remain substantially uniform during this period and not vary as would otherwise be the case were the supplied current to continually vary.

Figure 4 illustrates the power monitor unit 15. Like items, as between Figure 3 and Figure 4 have been assigned like reference symbols for the purposes of consistency. The functional and structural description of like items referred to above with reference to Figure 3 applies equally to the corresponding items in Figure 4.

Figure 4, the ballast circuit 11, a ballast inductor 20 (L) capacitor 21 (C) thereby collectively forming a series LC-resonant ballast circuit. Capacitor 22 creates a low pass DC averaging for the passive half of the bridge configuration, it plays no part in the tuning of the resonant circuit.

The ballast circuit 11 and the discharge light 13 are both connected to the monitor unit 15 such that the former and the latter are connected to the grounded terminal GND via the suppression filter of the monitoring unit 15. The monitoring unit has a first signal input 100 connected to the output terminal of the ballast circuit 11, this being the terminal of the capacitor C of the ballast circuit which is other than the terminal thereof connected to the ballast inductor 20. In addition, the monitoring unit has a second input 200 connected to the output terminal of the electron emitter filament 14 of the discharge light being the electrode of the discharge light not directly

connected to the ballast inductor 20. Thus, the first and second input terminals, 100 and 200 respectively, of the monitor unit 15 respectively receive the electrical current concurrently output by the ballast circuit 11 and the discharge light 13 respectively.

These simultaneously received currents are mixed by the high frequency suppression filter of the monitor unit which comprises a first filter arm consisting of a diode 25 biased to prevent current flowing other than into the suppression filter along that arm, and a first resistor 26 subsequent to the diode 25. A second filter arm comprises a resistor 23 and terminates at a grounded terminal GND. A third resistor connects the first filter arm, at a point intermediate the diode 25 and the first resistor 26, to the second filter arm at a point subsequent to the second resistor 23. A filter capacitor 27 connects the terminal end of the first filter arm (subsequent to the first resistor 26) to the terminal end of the second filter arm (subsequent to the point of connection thereupon of the third resistor 24) thereby connecting the terminal ends of the first and second filter arms collectively to the same grounded terminal GND. Each filter arm is connected to both of the first and second monitor input terminal (items 100 and 200). The result is a mixing of the currents output by the ballast circuit 11 and the discharge light 13 simultaneously, the subsequent filtering of the mixed currents, and the ultimate sensing of the filtered mixed currents at a current sensor 28 operatively connected to the output of the suppression filter between the first resistor 26 of the first filter arm and the filter capacitor 27 inter connecting the first and second filter arms. The filter circuit 15 serves several purposes;

firstly it creates a common total energy sense point that is sensed by the controller, secondly it allows the reference to be sensed at a ground point that is positioned close to the controller and therefore contains
5 minimum spurious signals, thirdly it means that the sense converter process can detect in a single sample the value presented (if there were no close coupled high frequency filter then there is every chance of a noise spike being processed as the actual value, this would lead to major
10 problems in any correction response).

Upon sensing the combined, mixed output current at the sensor 28 of the monitor unit 15, the value of the sensed current is digitised in an analogue to digital converter
15 of the monitor unit (not shown), and the digitised sensed current value is transmitted to the MPU control unit 17 via the communication link 16 for subsequent recording, averaging and comparison with predetermined "normal" values of the combined current stored within the MPU
20 control unit.

Exemplary modes of operation

Examples of a preferred mode of operation of an
25 embodiment of the present invention (in any one or more of its aspects) shall now be described.

The nature of the voltage and current drive signals delivered to the discharge light by the ballast circuit
30 11 are sensitively dependent upon the nature and form of the AC signals delivered to the ballast circuit 6 by the inverter circuit 7 in use. In order to provide optimal control of the waveform of the AC signal delivered to the ballast circuit, the generation of the positive-polarity

parts and the negative-polarity parts of the inverter output signal are separately and individually controlled such that opposite polarity parts may be independently formed.

5

Like items, as between Figure 3, Figure 4 and Figure 8 have been assigned like reference symbols for the purposes of consistency. The functional and structural description of like items referred to above with reference to Figure 3 and Figure 4 applies equally to the corresponding items in Figure 8.

Figure 8 schematically illustrates the means by which such waveform control is effected. The MPU control unit 15 17 includes a first control signal generator in the form of a first programmable pulse-width modulator (PWM) 260 and a separate second control signal generator in the form of a second programmable pulse-width modulator (PWM) 270 each being arranged to separately generate first and second inverter control signals respectively. Each of the 20 first and second control signal generators is programmable to exist in either an active state in which a generator output is produced thereby, or in an inactive state in which no generator output is produced thereby.

25 The inverter controller further includes a programming unit in the form of a micro-processor unit (MPU) 280 in separate communication with each of the first and second PWMs via respective data links 290 and 300. The MPU is arranged to successively re-program each of said first and second control signal generator means so as to 30 alternate between an active state and an inactive state. Obviously, an inverter control signal is generated according to the presence and absence of such control signal generator outputs.

The MPU control unit 17 is arranged to input the first and second inverter control signals (320 and 310 respectively) to the inverter 7 via separate respective control signal input channels 240 and 250 which collectively define the communications link 18. The high-side 9 of the inverter, responsible solely for the generation of positive-polarity parts of the inverter output, is therefore directly connected and in communication with only the first of the two separate PWM control signal generators 260. Similarly, the low-side 10 of the inverter, being responsible solely for the generation of negative-polarity parts of the inverter output, is in direct communication with only the second of the two PWM control signal generators 270.

15

The high-side 9 of the inverter generates a positive polarity pulse in response to the presence thereof of a first control signal pulse from the first PWM 260 and outputs the pulse at a high-side output port 220.

20 Similarly, the low-side 10 of the inverter generates a negative polarity pulse in response to the presence thereof of a second control signal pulse from the second PWM 270 and outputs the pulse at a low-side output port 230. Concurrent outputs at the low-side and high-side output ports are combined and output as the inverter output signal 8 at any given point in time. Thus,

appropriate shaping and timing of the PWM control signal pulses, and therefore of the high-side and low-side outputs of the inverter, determines the form of the inverter output.

5

Figure 9 schematically illustrates an example of the relative timings of the first ($V_{first}^{(+)}$) and second ($V_{second}^{(-)}$) inverter control signals. While Figure 9 illustrates relatively uniform square-wave type control pulses, it is to be understood that the first and second control inverter signals may be generated other forms in such a way as to control any of the amplitude, frequency, phase, shape or energy of any single cycle of the alternating output of the inverter means.

15

Each of the first and second inverter control signals comprises a train of control signal pulses as illustrated in Figure 9. The inverter control means is arranged to generate successive control signal pulses of the two separate inverter control signals alternately such that any control signal pulse of any one such inverter control signal is present only if a control signal pulse of the other such inverter control signal is absent thereby avoiding the temporal overlap (or interference) of the former with the latter.

25

This is achieved by the MPU programming unit 280 which is arranged to alternately prevent one of the first PWM 260 and the second PWM 270 from generating of a control
 5 signal pulse (e.g. pulse 330 of Figure 9) while simultaneously causing the other of the two PWMs to generate such a pulse (e.g. pulse 340 of Figure 9). Each of the first and second PWMs is programmable between an active state in which a signal, $V_{first}^{(+)}$ and $V_{second}^{(-)}$
 10 respectively, is output thereby, and an inactive state in which no signal is output thereby. The programming unit MPU 280 alternately re-programs the first and second PWMs to be either in opposite such states, or to be concurrently in an inactive state. The programming unit
 15 MPU 280 contains software programmed to assign a control period of duration T alternately to the first PWM 260 and the second PWM 270. During a given assigned control period T, one PWM is held inactive (no output) while the other PWM is programmed by the MPU to become active
 20 (output produced). However, before the given control period T expires, the software within the MPU adjusts the duration of the control period T to be a shorter control period $T' = T - \Delta t$ and re-programs the currently active PWM, but not the currently inactive PWM. Consequently, at a
 25 time T' the currently active PWM becomes inactive while

the other inactive PWM remains so for a further "dead-time" time period Δt . The MPU then returns the control period to a value T and repeats the above procedure in respect of the other of the two PWMs (i.e. the two PWMs swap roles).

The result is that either a first control signal pulse 330, or a second control signal pulse 340, or no control signal pulse is generated by the inverter controller at any given time. Notably, the concurrent generation of both a first and a second control signal pulse is avoided.

The result is that the duration of control signal pulses alternately generated by the first and second PWM are controlled to provide a variable "dead-time" (Δt_i , $i=1,2,3...$) between successively generated such pulses during which no control signal pulse of either of said two separate control signals exists. Each individual dead-time may be separately chosen by the MPU 280 so as to manipulate the waveform of the control signals separately and of the alternating output 8 (waveform V_{out} of Figure 9) of the inverter circuit.

With this control ability it is possible to generate appropriately timed excitation pulse signals which are then input into the discharge light via the ballast circuit. The time between successive rising edges of the high-side PWM control signal determines the frequency of the inverter AC power signal. The timing form of these PWM drive signals are caused to change dynamically in

response to the needs of the feedback circuit 15. The basic modes of control are; pre-ioniser sweep start-up, the post ionisation ramp-up, full power running condition, first phase dimming, second phase dimming and
5 inverter shut-down. In support of most modes there is the underlying safety protection monitoring that are required to provide general defence against inverter over current, inverter over voltage and mains supply under voltage.

10 Pre-ionisation sweep start-up mode:

The first of the control modes of the present embodiment uses the inverter control means of the ballast controller to control the inverter circuit 7 so as to be greater
15 than the resonance frequency of the ballast circuit 11 by an amount sufficient to prevent operation of the discharge light, and to subsequently reduce the frequency of the inverter output signal until the discharge light becomes operational or a predetermined fault condition
20 limit is reached.

Thus, the inverter control means may be arranged to control the start-up of the discharge light in a manner which avoids simply applying a large instantaneous strike
25 voltage to the discharged light in an attempt to cause the light to ignite. Consequently, the damaging effects of applying such large instantaneous strike voltages upon the circuitry of the ballast controller, the ballast circuit and the components of the discharged light are
30 avoided. Additionally, by sweeping through successively lower frequency values, and thereby gradually increasing the magnitude of the voltage delivered across the discharge light by the ballast circuit, the inverter control means is able to accurately search for the value

of the strike voltage which is just enough (but no more) to cause the discharge light to ionise and become conductive.

5 Referring to Figure 2, the frequency response one of the ballast circuit 11, as connected to a discharge light 13 in a non-conducting state (i.e. switched off), possesses a resonance at signal frequency ω_{res} which is less than the signal frequency ω_0 of the AC signal output by the
10 inverter circuit 7 (as controlled by the MPU control unit 17). In accordance with the resonance profile 1 of the ballast circuit 11, the voltage 3 delivered by the ballast circuit 11 to the discharge light 13 in response to an AC inverter output signal of frequency ω_0 , is less
15 than the strike voltage V_{strike} at which the discharge light 13 would be caused to ionise. The MPU control unit 17 generates control signals which, when input to the inverter circuit 7 cause the frequency of the signal output thereby to steadily reduce in value. The power
20 monitoring unit 15 periodically samples the electrical current passing through the ballast circuit in response to the inverter AC signal input to it, and communicates the sampled values to the MPU control unit 17. The received sample values are compared with predetermined
25 values associated with, or indicative of, the discharge light gas in a conductive state (i.e. switched on, plasma created). Should this comparison indicate that the discharged light has not ionised, the MPU control unit causes the frequency of the inverter AC output to further
30 reduce towards the resonance frequency of the ballast circuit thereby increasing the voltage delivered by the ballast circuit to the discharge light. This process continues until the monitored value of the current passing through the ballast circuit is found to be

indicative of the ionisation in the discharge light (sensed current suddenly reduces). At this point the frequency of the AC inverter output signal has reached a value ω_{strike} which is sufficiently close to the resonance frequency of the ballast circuit as to generate a voltage V_{strike} across the discharge light 13 sufficient to cause ionisation thereof. When this condition is reached, the MPU control unit 17 halts further reduction in the frequency of the inverter AC output signal.

10

Consequently the steady downward sweeping in signal frequency has the benefit of providing a high voltage ramp-up along a gentle slope towards the strike voltage value, thereby reducing stresses on the circuit components of the signal inverter, the ballast circuit and the discharge light. It is to be noted that the value of the strike voltage is effectively the minimum value of voltage at which strike occurs across the particular discharge light 13 used. This is in contradistinction to existing ignition systems which apply an instantaneous and very large strike voltage which is often larger in magnitude than is actually required to cause the discharge light to ignite.

25 As a safety measure, the MPU control unit is also operable to prevent further reduction in inverter output frequency, during the downward frequency sweep, if it is determined (via the monitor unit 15) that a maximum safe current/voltage has been reached in the sense that exceeding these would damage or destroy the inverter circuit.

30

An important aspect of this mode is that the operational point at which the discharge light will ionise (strike)

is not necessarily the point at which the continuation of the same will operate the light at its maximum energy level. Indeed it is generally the case that following the onset of the strike further operational changes will be required to reach maximum radiate light output from the discharge light.

Post-ionisation ramp-up mode:

The second of the control modes embodied herein uses the inverter control means of the ballast controller to control the inverter circuit 7 to safely transition the discharge energy from the strike state to the maximum energy state.

15

Following the ionisation sequence the energy level in the discharge light will be a value suitable to maintain a fully formed plasma but this will not necessarily be at the maximum radiate energy possible. The present embodiment then uses at least the first aspect of the invention to achieve this, the method is as described previously and is the phenomenon discovered by the inventor that the discharge tube can be more efficiently operated if the wave shape of the inverter output is allowed to be a slope-edged square wave as is possible using a inductor that is pushed into its saturation point.

In the current embodiment of the invention this means that the inverter operated through an LC ballast which is set to resonate at approximately 61KHz. This value is not key but does represent a value that is nether to low so as to cause the passive components to be larger than necessary and not to high that the electromagnetic losses

become significant. To keep the operation from excessive current loads the place that is traditionally used to operate the inverter would be slightly above this say 63-65KHz. At this frequency the discharge light will be
5 operating at the most stable condition as its impedance will "damp" the resonance when voltage across the C element changes these changes will be balanced by the negative impedance of the discharge light itself. However, in the present embodiment this is reversed to
10 below the resonant value. In the case of the current embodiment it is set at 60HKz. This is not the most efficient frequency only the most stable the inductor is designed to slightly under-run the energy to the light by about 10%.

15

Full power running mode:

The third of the control modes of the present embodiment uses the inverter control means of the ballast controller
20 to maintain the discharge light at the optimum maximum energy state.

To reach the maximum radiate light output the inverter frequency is reduced fairly quickly, say within 100mS, to
25 a value where the saturation increases the current through the ballast and light to a predetermined value which represents the maximum current safely allowed. The point at which this occurs is not stable, the discharge light is operating on the verge of entering the 3rd phase of
30 discharge - ark. If the light is allowed to enter the ark phase, current will increase suddenly, the resistance of the plasma drops to a fraction of the glow discharge state and the voltage required to sustain the ark is much lower than the glow required. In this state the super

conducting plasma will rapidly damage the electrodes by spot pitting and the conduction element, mercury or xenon, will be absorbed. The very high currents will also overload the inverter and cause destruction of the power driver transistors.

As the stability becomes more critical, as the flat current state is extended, it becomes more and more difficult for the power controller device, the MPU, to maintain the safe margin. It is this that determines the below resonance high efficiency limit of the present embodiment. The closer to the edge of the ark state the more efficient will be the energy conversion. Fluorescent discharge lights are already very efficient at energy conversion and the degree of improvement available is fractions but as any improvement represents lower energy consumption and therefore ultimately lower CO² emission to produce the same radiate light output it is a very desirable effect.

20

The ability to hold the ballast in this region is made possible only by maintaining the delivered energy within as constant band as possible. It has already been described how the invention manages this by multiple properties of AC and DC power signals being monitored on a cycle-by-cycle and other aspects of the present invention, the most pertinent being predictive compensation. The overall goal is try to keep the energy within any cycle to better than 2% of any other at that average power state. The process described here is very much affected by temperature within the discharge light itself and time compensation must also be used to allow for the fact that the tube will only run at peak efficiency at around 40°C (measured at the electrode

points) below this temperature and the tube is less stable and the region of improved efficiency is much reduced. This change must also be compensated for when the discharge light is operated in any dimmed level as
5 the heat inside the light will be equally reduced.

In a further enhancement of this aspect the discharge light could be operated in near DC energy drive. Fluorescent lights are operated by AC energy for several
10 reasons not least of which is that the ballast has to be AC to function. On top of this is the fact that if DC were used then the ionisation plasma field would always flow in same direction. This would cause the cathode (negative) end to be darker than the positive (anode) end
15 due to the formation of various so called rings, these in the cathode dark space, the Faraday dark space and the Aston dark space. This would look odd but worse is that the cathode electrode would be eroded at twice the rate so reducing the light life expectancy.

20

The advantages of operation at DC levels are strong as the conversion rate would be optimal but the disadvantages have always made this a non-starter. However a further possibility using this invention opens
25 up a potential opportunity to operate the light in a slow AC being a virtual DC mode. This aspect being stabilised by high speed rectified PWM which achieves the DC requirements but is direction flipped at low speed to achieve the best discharge light endurance, this process
30 being handled by the intelligent power controller in each direction.

Discharge light dimming method:

A preferred method of discharge light dimming according to a preferred embodiment of the invention shall now be described.

5 There are two principal prior art dimming methods currently known: firstly varying the source DC supply voltage to the AC inverter; and secondly reducing the active period of the energising AC pulses to the inverter. These both produces less available energy in
10 the resonant circuit and leads to the peak current through the discharge lamp reducing, because of the negative resistance of the tube, this causes the current to decrease. This is an effective method but the problems are that to maintain the plasma the heaters must always
15 be used and must preferably stay at the same current as they experience at full power. This is because the heaters are used to excite the gas within the light so that less potential is required to maintain the conduction plasma. Another disadvantage of this method is
20 that the power conversion is less efficient in the inverter and there are more electronic circuits required which also create loss in the form of heat, the collection effect of this is dimming but without saving equivalent supply energy, this is not desirable when the
25 goal is to save power and therefore CO² gases.

First phase dimming mode:

The fourth of the control modes embodied by the present
30 invention, uses the inverter control means of the ballast controller to control the inverter circuit 7 to safely transition from the maximum energy state to the initial reduced energy states.

At the start of the first stage of dimming the discharge light is operating at the below resonance compensated state. The first sequence of dimming is to move from this full power state to the close resonant state where the inductor and capacitor of the resonator will provide the maximum stabilisation for changing load conditions. It has already been stated that the difference between these two power states is approximately 10% so the power controller adjusts the inverter AC power signal such that the average frequency is increased until it is just below the natural resonant frequency of the ballast. This can be effected by variable or fixed step means. In the current embodiment of the invention this is performed by using two predefined steps taking the AC frequency from approximately 40KHz to 61KHz this produces a actual measured reduction of 13%.

Second phase dimming mode:

The sixth of the control modes embodied by the present invention, uses the inverter control means of the ballast controller to control the inverter circuit 7 to safely transition from the first phase of energy reduction to the minimum practical reduced energy state.

At the start of the second stage of dimming the discharge light is operating at just below the resonance frequency. This second sequence of dimming is performed by a technique that uses separated AC inverter output pulses having a frequency equal to (or a multiple of) the resonance frequency of the ballast circuit.

To allow these single pulses to be generated, the inverter is controlled generate resonant excitation

pulses according to the resonant "ringing" periods of the ballast circuit. A resonant circuit, when excited by a pulse at the resonant frequency, will naturally ring (resonant) at that frequency as the energy is switched
5 back and forth between the inductor and capacitor. If a further pulse were applied when this ringing was at an opposite state to that of the applied pulse, then unnecessarily damaging large currents would be forced to flow through ballast and driver transistors. To further
10 explain this, if the resonant circuit were swinging negatively, due to ringing, in the negative half cycle and the inverter switched its positive transistor on there would be a large difference between the two energy points that would have to be instantly equalised. This
15 causes (at the very least) EMC emissions as the electronic circuit generates high energy noise which would be undesirable, and (at worst) the energy would be so great that the output transistors would be overloaded by the direct currents or the general heat generated
20 leading to their early failure.

Thus, preferably, the excitation pulse signal is input to the discharge light preferably only when the inductor is close to, or at, the zero energy state. At this state the
25 new pulse injection will not have to absorb any of the demagnetising energy from the inductor. This will naturally induce a single cycle that is power efficient and allows the inductive-capacitive (LC) ballast circuit to use the full pulse period to generate gain. This means
30 that the voltage so generated across the capacitor (C) of the inductor capacitor pair is maximised at a time when the fluorescent light begins to experience a gradual collapse in its plasma as the average energy delivered is reduced. It has been found that the increase in the

voltage across the light that maintains a discharge at the lower average energy may be as much as three times the voltage at the full radiate power level.

5 Thus, therefore, to allow the dimming technique to function optimally, the excitation pulses are most preferably appropriately temporally spaced by the power controller such that they are applied to the ballast circuit during the correct phase (positive or negative)
10 of a ringing cycle within ringing ballast circuit, and that the ballast energy level is as close to zero as possible at the instant of excitation pulse injection.

Using this second phase of dimming technique the power
15 controller may use the power savings associated with the present dimming method to form part of an overall energy conversation scheme. To deliver the second phase of dimming the power controller adjusts the inverter AC power signal such that a single excitation pulse, of the
20 same frequency (duration) as that of the excitation pulse generated at the end of the first phase of dimming, is generated by the inverter.

Then by increasing the time period between successive
25 pulses the average energy delivered to the discharge light is reduced. The gap between pulses is adjusted by the power controller to ensure that the pulse is injected at the correct "ringing" phase point of ballast circuit as described above. Otherwise, the interval between
30 successive excitation pulses may be varied in predetermined steps or may be continuously variable states. As the average energy delivered to the light is reduced, so too is the amount of heat generated within

the discharge light itself. This reduction in heat only aids the operation of the technique.

Shut-down mode:

5

The seventh of the control modes embodied by the present invention, in another of its aspects, uses the inverter control means of the ballast controller operative using the means previously described, to place the inverter circuit 7 in a stable non-operating state which best minimises energy consumption.

This mode includes controlling the inverter to place the ballast circuit, and therefore the discharge light itself, into an un-powered state. This is accomplished by halting signals to both drive transistors of the inverter and allowing the resonator of the ballast circuit to relax. This means that all drive signals and monitoring circuits are at zero energy levels. The power controller is preferably still operable during the un-powered state and arranged to monitor any the communications interface, and/or manual control inputs, and/or infrared sensing inputs (discussed below) it may possess.

25 When in the un-powered state, the supply power consumption of the power controller is virtually zero making this a very important state in an overall low power secondary lighting scheme. When it is required to return from this leave the un-powered state, the turn-on sequence may go through the full power-up process as described above.

The networking of power controllers:

An example of the networking (collective control) of a plurality of power controllers of the present invention shall now be described.

5 In a further embodiment of the present invention the ambient illumination monitor 92 of the power controller is arranged to monitor environmental/operational conditions in the environment of the discharge light 13, and to communicate the monitored conditions to the MPU
10 control unit 17 via the communication link 94 connecting the former to the latter. The programming unit MPU 280 of the MPU control unit 17 is a re-programmable micro-processor unit arranged to process software which, when processed, generates control signals for use in
15 controlling the inverter AC power signal 8 generated by the inverter circuit 7 thereby to adjust the power delivered to the discharge light 13 via the ballast circuit 11.

20 The programming MPU 280 is operable to re-program itself according to the environmental/operating conditions as determined by it according to the monitor unit 92 responsible for monitoring those conditions. Thus the programming MPU 280 is able to modify the software
25 contained within it such that, when processed thereby, it generates accordingly modified control signals for use in controlling the AC power signal output by the inverter circuit 7 activating a level within the dimming phases described previously.

30

Alternatively, or additionally, the monitoring unit 92 is arranged to receive specific re-programmed signals from a user in response to which the re-programmable MPU 280 is operable to re-program itself. This direct re-programming

function is preferably effected remotely using infra-red (IR) communication means for conveying the re-programmed signal from the user to the power controller.

- 5 The power controller is operable to re-program in response to changes in the monitored operational/environmental conditions monitored by the monitoring unit 92. For example, the MPU control unit 17 may contain software to enable it to appropriately re-
- 10 program in response to predetermined changes in properties of the DC power input to, or the AC power output from, the inverter circuit 7, or changes in the ambient illumination level at the location of the discharge light 13. The software contained within the MPU
- 15 control unit may also be re-programmable thereby in response to the detected presence of other power controllers, such as the one presently described, within the environment of the power controller in question.
- 20 Thus, the re-programmable power controller is able to re-program itself as it determines necessary in order to adapt to changes in the operating environment. For example, if it is detected that the DC power input level 6 to the inverter circuit 7 is subject to random
- 25 fluctuations, the MPU control unit 17 contains software enabling it to re-program itself in order to adapt the control methodology by which it compensates for DC signal input power variations. More particularly, when the power controller detects that other such power controllers are
- 30 present within its operating environment, the MPU control unit is operable to re-program itself to enable it to control the inverter circuit 7 according to the operating conditions of the other of the power control units. In this way, a plurality of power control units is able to

operate collectively as a network of inter-communicating power controllers.

This communications is preferably performed by using an
5 on-board low voltage isolated single wire data signal. Across this data link may be sent commands under a general protocol known to some/all such power controllers such that they are able to nominate a single master that will act as the centre controller for the network so
10 formed. Preferably, only one such member of a network would then provide the ambient light monitoring function and communicate information regarding (or resulting from) that monitoring to all members so connected. With this data link, multiple power controllers may be arranged to
15 coordinate a strategy/method for controlling the ambient light level within a given region/area (e.g. the zone occupied by the coordinating controllers). Multiple zones of mutual coordination may be so formed in the same way and these zones linked/inter-networked by similar data
20 link to form a total environmental solution for light within any space.

An further or alternative use of the internetworking method and apparatus described herein is the remote/local
25 control of remotely or locally control a large space so as to reflect the needs of the usage of that space. The power controllers of the network may be arranged to accept manual or automated command inputs to set zoned
light levels or target ambient conditions or basic on/off
30 requests. A further enhancement of this communications link is that information may be sent from the power controllers as well as to them. In this way individual power controllers may be arranged to communicate (report) their operating conditions, including faults and

configuration settings, back to a local or remote logging or monitoring point/location/facility. This may include details of current and past power consumption levels directly read from the individual power controllers themselves. This permits an interactive and dynamic maintenance/ performance system.

This collective/network reprogrammability permits a plurality of power controllers to operate according to a collective light-management strategy whereby the radiant output power of each discharge light of the network of lights is controlled according to the radiant output power of the others of the network. This collective management may be a common software means contained within each controller of the network which, when processed, causes collective light operation so as to produce the optimal/desired collective light output.

Separate power controllers within such a network may communicate their individual operating conditions, and their respective monitored environmental operating conditions, to each one of the other power controllers within the network. This inter-controller communication may be effected, for example, via wireless (e.g. infrared (IR)) communications techniques.

Referring to Figure 11, the ballast circuit 12 contains an inductor L across which a back-e.m.f. (V_L) is generated in response to the a.c. power signal 8 delivered to the ballast circuit by the signal inverter circuit 7. In this embodiment of the present invention, the power monitor means 15 of the power controller is arranged to

monitor the inductor voltage V_L generated across the inductor L in response to the a.c. power signal. The power monitor 15 periodically samples the inductor voltage V_L and delivers the sampled results periodically to the MPU control unit 17 via the communication link 16 between the power monitor and the MPU control unit. This monitoring function of the power monitor means 15 may be in addition to, or instead of, any of the power monitoring functions of the power monitor means discussed above.

In response to the monitored values V_L so received, the programming unit MPU 280 of the MPU control unit 17 determines whether or not the received sample value of the inductor voltage is both below a pre-set threshold value and is falling in magnitude. When the programming unit MPU 280 determines both of the latter conditions to be present, it programs each of the first and second PWMs, via respective data links 290 and 300, to generate appropriately timed first and second inverter control signal pulses (320 and 310 respectively) for input to the inverter circuit 7 via separate respective control signal input channels 240 and 250 which collectively define the communications link 18 (see Figure 8).

The programming unit MPU 280 controls the first PWM 260 to generate a single control pulse, and the second PWM control signal generator 270 to generate a substantially immediately successive single second inverter control signal pulse. In response to receipt of the first and successive second single control signal pulses, the inverter circuit 7 generates a single square-wave excitation pulse which is output concurrently with the a.c. power signal output thereof.

10

Referring to Figure 5, there is schematically illustrated a plot of the inductor voltage V_L generated across the inductor L of the ballast circuit 11 in response to the a.c. power signal 8 from the inverter circuit 7, together with the electrical current waveform I_{pulse} of excitation pulse signals generated by the inverter circuit 11 in response to the aforementioned control by the MPU control unit 17.

20 Two excitation current pulse signals (80 and 81) are illustrated. Each excitation current pulse signal is square-wave in nature and has a complete cycle period T_p which accords the excitation pulse in question a pulse frequency equal to the resonance frequency ω_{res} of the ballast circuit 11, namely:

25

$$T_p = 2\pi / \omega_{res}$$

Consequently, the power delivered to the discharge light 13 in response to each excitation pulse signal (80 or 81) via the ballast circuit 11 is optimised by this choice of excitation pulse signal frequency. Each excitation pulse signal begins at a point in time substantially coincident with the monitored magnitude of the inductor voltage V_L falling to a value substantially equal to 0 (zero). Thus the first excitation pulse signal 80 is generated by the inverter circuit 7 changes from positive to negative values, while the second excitation pulse signal 81 is so generated when the inductor voltage V_L subsequently changes from negative to positive values during the cycle of the a.c. power signal 8. Thus, the time interval T_L between successive excitation pulse signals is substantially equal to one half of the cycle period of the a.c. power signal generated by the inverter circuit 7.

20

In practice, a given excitation pulse is generated when the magnitude of the inductor voltage V_L falls below a preset threshold value which is sufficiently small as to be indicative of the inductor voltage being effectively 0 (zero). This predetermined threshold value is stored within the MPU control unit 17.

25

Thus, the appropriately timed generation of excitation pulse signals and their input to the discharge light via the ballast circuit causes the ballast circuit to
5 generate a voltage across the discharge light sufficient to maintain the discharge light in a conductive state while the magnitude of the inductor voltage V_L remains below the predetermined threshold value. This energy injection to the discharge light enables significant
10 reductions in the voltage applied across the discharge light, thereby to allow the discharge light to be "dimmed", without suffering plasma drop-out.

It is to be noted that through the use of judiciously
15 timed and shaped excitation pulse signals (80 and 81) the discharge light 13 may be driven, and adjustably dimmed, using an a.c. power rating which is significantly lower than would be required in order to avoid plasma drop-out within the discharge light were the excitation pulse
20 signals not employed. This is a significant energy saving.

It is also to be noted that the present reversible dimming facility may be affected without the use of
25 heater circuitry or methods for heating the electron emitter filaments of the discharge light as is typically

employed in prior art systems to attempt to enable the use of lower voltages without plasma drop-out across a discharge light.

5 By injecting excitation signal pulses into the ballast circuit (and therefore via the ballast inductor L) when the ballast voltage V_L is substantially 0 (zero), or very nearly so, the present invention is able to inject the required energy pulse to the discharge light 13 not only
10 at a time which is optimal for preventing plasma drop-out in the discharge light, but also which is optimal for the efficient transfer of energy from the inverter circuit 7 to the discharge light 13. This is because when the voltage (V_L) across the inductor is (or is near to) zero,
15 the excitation pulse signal experiences minimal opposition to its transit through the inductor. This means that the energy contained within each excitation pulse signal need not be significantly more than is required to prevent plasma drop-out within the discharge
20 light 13 since little energy is lost in overcoming opposition from a substantially absent voltage (V_L).

In a further embodiment of the present invention, the power controller additional (or alternatively) includes a
25 light monitoring means 92 arranged to monitor the ambient illumination level 93 in the vicinity of the discharge

light 13, and to communicate the monitored illumination levels to the MPU control unit 17 via a communications link 94. In such an embodiment, the MPU control unit 17 is operable to adjust the frequency of the a.c. power signal 8 generated by the inverter circuit 7 so as to adjust the power delivered to, and ultimately radiated by, the discharge light 13 thereby to control the ambient illumination level in the monitored vicinity of that discharge light. This control may be achieved according to control of the first and second PWMs of the MPU control unit 17, as controlled by the programming unit MPU 280 as discussed above.

The MPU control unit 17 may have stored within it any number of predetermined illumination levels (or "dimming" levels) with which the monitored ambient illumination level is compared thereby. The control unit may be, for example, arranged to adjust the power delivered to the discharge light 13 in response to the monitored ambient illumination levels so as to maintain the ambient illumination level at one of the stored "dimming" level values. This auto-dimming feedback control link enables the power controller to cause the discharge light to generate only the required illumination for the vicinity of the discharge light and no more, thereby providing a responsive and energy-efficient discharge lighting

system. The power controller may turn off the discharge tube completely when monitored values of ambient illumination indicate that no illumination is required from the discharge light 13. In this condition, the illumination monitor 92 continues to be operational, as does the power controller, such that when ambient illumination levels subsequently fall, and it is determined that illumination from the discharge light 13 is required, the power controller is operable to re-start the discharge light 13 thereby to enable the discharge light to assist in maintaining the required illumination levels. Of course, the discharge light may be ignited and subsequently operated according to any of the methods and apparatus described above in respect of any of the other aspects of the present invention.

A further embodiment of the present invention is now described with reference to Figure 10 and Figure 11. Referring to Figure 12, the power controller includes a d.c. power monitor 95 arranged to monitor the d.c. power input to the inverter circuit 7, and to communicate the monitored values of the d.c. power to the MPU control unit 17 via a communications link 96 connecting the former to the latter. The MPU control unit is arranged to monitor variations in the monitored d.c. power input level, and to vary the frequency of the a.c. power signal

8 generated by the inverter circuit 7 in response to detected variations in the d.c. power input 6. In this way, the MPU control unit 17 is arranged to control the a.c. power signal 8 delivered to the discharge light 13 via the ballast circuit 11 so as to minimise variations in the power supplied to the discharge light resulting from variations within the d.c. monitored power input level.

10 For example, referring to Figure 10, there is illustrated a very simplified schematic plot 90 of monitored values of the d.c. signal 6 input to the inverter circuit 7 as monitored by the d.c. monitor unit 95. The d.c. signal 90 is not constant and rises above or falls below a threshold value TH representative of an average d.c. signal level. During a first time interval A, the d.c. level (dashed curve) is below the threshold TH, and subsequently is above that level during the following period B. The d.c. level subsequently is below, above, and once more below the threshold level TH during the subsequent successive time periods C, D and E respectively. Consequently during time periods A, C and E, the d.c. signal level supplied to the inverter circuit 7 and therefore the amplitude of the a.c. power signal 8 generated by and output from the inverter circuit is below the threshold level TH. Conversely during the

intermediate periods B and D, the power level input to, and the amplitude of the a.c. signal output from, the inverter circuit 7 is above the threshold value TH.

Thus, the periodic variations in the d.c. signal level 90
5 results in correspondingly periodic variations in the amplitudes of the a.c. power signal a.c. delivered to the discharge light via the ballast circuit 11. These power variations may be visible as variations in the radiant power output of the discharge light 13, and thereby
10 producing a perceptible light output flickering effect.

In order to compensate for the resultant peaks and troughs in power delivered to the discharge light, the MPU control unit 17 is operable to control the frequency
15 of the a.c. signal generated by the inverter circuit 7 in response to variations in the monitored d.c. power input level so as to minimise variations in the power supplied to the discharge light via the ballast circuit. This variation is done according to the frequency response of
20 the ballast circuit whereby the MPU control unit generates inverter control signals which cause the inverter to change the frequency of its a.c. power output signal to recede from the resonance frequency value of the ballast circuit when the d.c. power input is below
25 the threshold value TH, and to cause the inverter a.c. power output signal frequency approach the resonance

frequency when the d.c. power exceeds the threshold value TH. In the present example, the inverter circuit 7 is controlled to operate at frequencies below the resonance frequency of the ballast circuit 11 such that during the
5 time intervals A, C and E, the inverter circuit is controlled to generate an a.c. power signal of relatively lower frequency (i.e. the frequency recedes from the resonance frequency value, which is higher than the a.c. signal frequency value). Conversely, during the time
10 intervals B and D when the d.c. power level is above the threshold value TH the inverter output signal frequency is caused to increase and to move towards the resonance frequency value.

15 In this way, when d.c. power input levels are too large, the inverter output signal is caused to "climb-up" the resonance peak associated with the ballast circuit frequency response. Conversely, while the d.c. power input level is too low, the inverter output signal
20 frequency is caused to "climb-down" the resonance frequency profile. This reduces and increases the power delivered to the discharge light 13 via the ballast circuit 11 respectively thereby compensating for the oppositely-directed power variations in the input d.c.
25 power level.

The MPU control unit 17 is arranged to determine the oscillation period of each successive half-cycle of the variations in the input d.c. power level. That is to say, the control unit determines the duration and
5 location of the successive time intervals A, B, C, D and E. The MPU control unit is operable to vary the frequency of the inverter output signal so as to affect the appropriate change in power delivered to the discharge light 13 during the forthcoming cycle in the
10 d.c. signal variations. This is illustrated in the waveform 91 of Figure 10

Figure 7 schematically illustrates the output characteristics of a discharge light driven according to
15 prior art power control techniques and apparatus, together with the operating characteristics of the same discharge light when driven according to power control techniques and apparatus of the present invention at a.c. power signal frequencies below the ballast resonance
20 frequency.

Two sets of plots are illustrated in Figure 7, the upper set comprising the voltage across (V_1), current through (I_1), and light output of (X_1) a discharge light driven
25 according to a Philips BTA 58L31 ballast together with a phase correction capacitor fitted across an Osram L58W/835 white fluorescent discharge light.

The lower set of plots illustrates the voltage (V_2) generated across, the current (I_2) passing through, and the light output (bounded by lines X_2^U and X_2^L) produced by the same Osram fluorescent discharge light when driven according to power control methods and apparatus of the present invention. Here, the fluorescent light was driven at frequencies below ballast resonance as discussed above with reference to Figures 1 and 6. The drive frequency was controlled according to variations in d.c. power input to the driving signal inverter as described above with reference to Figure 11. Control signal pulses were used to control the drive frequency as discussed with reference to Figure 9.

As can be seen from the upper set of plots of Figure 7, the phase of the current I_1 passing through the fluorescent light in question still lags the phase of the voltage V_1 generated across that fluorescent light. This is so in spite of the presence of a phase correction capacitor having been employed with the Philips ballast. The waveform of both the voltage V_1 and the current I_1 is substantially periodic and substantially continuously varying. Consequently, the measured light output X_1 was also found to be broadly periodic in form possessing a dominant low frequency component with a number of very high frequency components superimposed upon the dominant

low frequency component. The low frequency component produces a flickering effect.

Conversely, the lower set of plots illustrates that the
5 discharge light voltage V_2 and current I_2 are not only brought into phase according to the present invention, but that each also shows much less distortion by virtue of the fact that the load is substantially constant across each cycle of those waveforms. The light output X_2
10 has had substantially removed from it the dominant low frequency component present within the light output waveform X_1 . Consequently, predominantly only the high frequency light output components remain within the light output signal X_2 such that the light output oscillates
15 rapidly between the upper output limit X_2^u and the lower limit X_2^l with little or no low frequency oscillations therein. Consequently, the light output X_2 shows very little or substantially no flicker. It is to be noted that the waveform of the discharge light current I_2 is
20 substantially flat during each "saturation period" T_s during which the current delivered to the discharge light is substantially constant. Additionally, the proportion of each cycle of the discharge light current I_2 during which the current undergoes significant changes in
25 magnitude (i.e. the periods in between each successive "saturation period") is relatively small, thereby

reducing visible flicker in the light output of the fluorescent light.

The steady state value of V_1 and V_2 was 230 volts (a.c.).
5 The corresponding steady state values of I_1 and I_2 were found to be 423mA a.c. and 226 mA a.c. respectively. The d.c. value of the light outputs X_1 and X_2 were substantially equal. Thus, the fluorescent light when driven according to the power control methods and
10 apparatus of the present invention was found to operate at a significantly lower power rating, produced significantly less flicker.

It is to be noted that in practice a time lag will exist
15 between the implementation of an inverter frequency change and the effect of that change becoming apparent upon the power delivered to the discharge light via the ballast circuit. The dotted DC signal curve of Figure 10 is purely for illustrative purposes, while the solid
20 curve 90 of Figure 10 more accurately reflects the relative phases (lag accounted for) between inverter output and input signals.

25

It is to be appreciated that modifications to or variants of any one of the embodiments described above, such as would be readily apparent to the skilled person, may be made without departing from the scope of the invention.

30

CLAIMS:

1. A method for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a predetermined value of the frequency of said alternating power signal, the method including;

maintaining the value of the frequency of said alternating power signal to be less than said predetermined value.

2. A method according to Claim 1 including monitoring the power delivered to the discharge light by the ballast circuit, and adjusting the alternating power signal in response to variations in the delivered power so as to stabilise the delivered power.

3. A method according to Claim 2 including monitoring the value of a selected property of the alternating power signal: as input to the ballast circuit; and/or, as present within the ballast circuit; and/or, as delivered to the discharge light, and deriving from the monitored value of the selected property a measure of the power delivered to the discharge light.

4. A method according to Claim 3 in which said selected property is the value of the electrical currents both as present within the ballast circuit and as concurrently delivered to the discharge light.

5. A method according to Claim 4 including comparing the values of said electrical currents present within the ballast circuit and concurrently delivered to the discharge light, to predetermined respective reference

values thereof, and deriving from said comparison said measure of the power delivered to the discharge light.

6. A method according to Claim 5 in which said
5 predetermined respective reference values are values corresponding with a predetermined value of power being delivered to the discharge light via said ballast circuit.

10 7. A method according to any of claims 3 to 6 including sampling values of said selected property of the alternating power signal once within separate successive sampling periods, wherein each sampling period is no
15 greater in duration than one half of the duration of a single cycle of said alternating power signal.

8. A method according to any of claims 2 to 7 including adjusting any one or more of the frequency, amplitude, or phase of the alternating power signal when adjusting that
20 signal in response to variations in the delivered power.

9. A method according to any of preceding claims 2 to 8 including adjusting the AC power signal according to the frequency response of the ballast circuit when responding
25 to variations in the delivered power so as to cause a stabilisation in delivered power.

10. A method according to any preceding claim including increasing the frequency of the AC power signal
30 in response to decreases in the delivered power, and to reduce the frequency of the AC power signal in response to increases in the delivered power, thereby to stabilise the delivered power.

|

11. A method according to any preceding claim including maintaining the frequency of the AC power signal at a value sufficiently low that during at least a part of a cycle of the AC power signal an inductor means
5 of the ballast circuit is caused to saturate, whereby the magnitude of the back-e.m.f. induced thereby is less than a predetermined threshold value during said part of said cycle.

10 12. A power controller for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a predetermined value of the frequency of said alternating power signal, including:

15 a power control means arranged to control the AC power signal to maintain the value of the frequency of said AC power signal to be less than said predetermined value.

20 13. A power controller according to Claim 12 in which the power control means is arranged to monitor the power delivered to the discharge light by the ballast circuit, and to adjust the AC power signal in response to variations in the delivered power so as to stabilise the
25 delivered power.

14. A power controller according to Claim 13 in which the power control means includes power monitor means arranged to monitor the value of a selected
30 property of the AC power signal: as input to the ballast circuit; and/or, as present within the ballast circuit; and/or, as delivered to the discharge light, and to derive from the monitored value of the selected property a measure of the power delivered to the discharge light.

15. A power controller according to Claim 14 in which said selected property is the value of the electrical currents both as present within the ballast circuit and as concurrently delivered to the discharge light.

16. A power controller according to Claim 15 in which said power monitor means is arranged to compare the values of said electrical currents present within the ballast circuit and concurrently delivered to the discharge light, to predetermined respective reference values thereof and to derive from said comparison said measure of the power delivered to the discharge light.

15

17. A power controller according to Claim 16 in which said predetermined respective reference values are values corresponding with a predetermined value of power being delivered to the discharge light via said ballast circuit.

20

18. A power controller according to any of claims 14 to 17 in which the power monitor means is arranged to sample values of said selected property of the AC power signal once within separate successive sampling periods, wherein each sampling period is no greater in duration than the one half of the duration of a single cycle of said AC power signal.

25

19. A power controller according to any of claims 13 to 18 in which the power control means is arranged to adjust any one or more of the frequency, amplitude, or phase of the AC power signal when adjusting that signal in response to variations in the delivered power.

30

20. A power controller according to any of preceding Claims 13 to 19 in which the power control means is operable to adjust the AC power signal according to the frequency response of the ballast circuit when responding to variations in the delivered power so as to cause a stabilisation in delivered power.

21. A power controller according to any of preceding Claims 12 to 20 in which the power control means is arranged to increase the frequency of the AC power signal in response to decreases in the delivered power, and to reduce the frequency of the AC power signal in response to increases in the delivered power, thereby to stabilise the delivered power.

22. A power controller according to any of preceding Claims 12 to 21 in which the power control means is arranged to maintain the frequency of the AC power signal at a value sufficiently low that during at least a part of a cycle of the AC power signal an inductor means of the ballast circuit is caused to saturate, whereby the magnitude of the back-e.m.f. induced thereby is less than a predetermined threshold value during said part of said cycle.

23. A power controller according to any of preceding claims 12 to 22 wherein an inverter means is arranged to receive a DC power input signal and to generate said alternating (AC) power signal therefrom for powering the discharge light via a ballast circuit, wherein the power control means includes an inverter control means arranged to generate inverter control

signals for controlling said inverter so as to control the AC power signal generated thereby.

24. A power controller according to claim 23
5 wherein said power control means includes said inverter means.

25. A method for controlling the power delivered to a discharge light by an alternating (AC) power signal via
10 a ballast circuit which resonates at a predetermined value of the frequency of said alternating power signal, the method including;

controlling the frequency of the AC power signal to be greater than the predetermined value by an amount
15 sufficient to prevent operation of the discharge light, and to subsequently reduce the frequency of the AC power signal until the discharge light becomes operational.

26. A method according Claim 25 including reducing
20 the frequency of the AC power signal continuously thereby sweeping through successively lower frequency values.

27. A method according to Claim 25 or Claim 26 including monitoring the value of a selected property of
25 the AC power signal either: as input to the ballast circuit; and/or as present within the ballast circuit; and/or as delivered to the discharge light, and halting reduction in the frequency of the a.c power signal when the value of the selected property is detected to have
30 reached a value indicative of the discharge light being operational.

28. A method according to any of claims 25 or 27

including monitoring the value of a selected property of the AC power signal either: as input to the ballast circuit; and/or as present within the ballast circuit; and/or as delivered to the discharge light, and halting
5 reduction in the frequency of the AC power signal when the value of the selected property is detected to have reached a predetermined threshold value.

29. A method according to Claim 27 or Claim 28
10 including halting reduction in the frequency of the AC power signal when the value of the selected property either: is detected to have reached said predetermined threshold value; or, is detected to have reached said
value indicative of the discharge light being
15 operational, whichever occurs first.

30. A method according to any of claims 1 to 11 and
25 to 29 including processing software arranged, when processed, to generate control signals for use in
20 controlling the AC power signal.

31. A power controller for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit which resonates at a
25 predetermined value of the frequency of said alternating power signal, including:

a power control means arranged to control the frequency of said AC power signal to be greater than the predetermined value by an amount sufficient to prevent
30 operation of the discharge light, and to subsequently reduce the frequency of the AC power signal until the discharge light becomes operational.

32. A power controller according Claim 31 in

which the power control means is operable to reduce the frequency of the AC power signal continuously thereby sweeping through successively lower frequency values.

5 33. A power controller according to Claim 32 in which the power control means is operable to monitor the value of a selected property of the AC power signal either: as input to the ballast circuit; and/or as present within the ballast circuit; and/or as delivered
10 to the discharge light, and to halt reduction in the frequency of the AC power signal when the value of the selected property is detected to have reached a value indicative of the discharge light being operational.

15 34. A power controller according to Claim 32 or 33 in which the power control means is operable to monitor the value of a selected property of the AC power signal generated either: as input to the ballast circuit; or as present within the ballast circuit; or as delivered
20 to the discharge light, and to halt reduction in the frequency of the AC power signal when the value of the selected property is detected to have reached a predetermined threshold value.

25 35. A power controller according to Claim 33 or Claim 44 in which the power control means is operable to halt reduction in the frequency of the AC power signal when the value of the selected property either: is detected to have reached said predetermined threshold
30 value; or, is detected to have reached said value indicative of the discharge light being operational, whichever occurs first.

36. A power controller according to any of claims

31 to 35 in which the power control means includes a processor means for processing software arranged, when processed, to generate control signals for use in controlling the AC power signal.

5

37. A power controller according to any of preceding claims 31 to 36 wherein an inverter means is arranged to receive a DC power input signal and to generate said alternating (AC) power signal therefrom for powering the discharge light via a ballast circuit, wherein the power control means includes an inverter control means arranged to generate inverter control signals for controlling said inverter so as to control the AC power signal generated thereby.

15

38. A power controller according to claim 37 wherein said power control means includes said inverter means.

20

39. A method for controlling the power delivered to a discharge light from a source of direct-current (DC) power, the power being delivered via a signal inverter and subsequent ballast circuit as an alternating (AC) power signal, the method including:

25

monitoring variations in the DC power input to the signal inverter, and varying the frequency of the alternating power signal according to detected variations in the DC power input, thereby to control variations in the power supplied to the discharge light via the ballast circuit.

30

40. A method according to Claim 39 including

varying the frequency of the AC power signal so as to minimise variations in the power supplied to the discharge light via the ballast circuit.

5 41. A method according to Claim 40 in which said variations in the frequency of the alternating output signal are made according to the signal response of the ballast circuit via which the alternating power signal is delivered to the light.

10

42. A method according to any of preceding claims 39 to 41 in which the ballast circuit has a frequency response which resonates at a predetermined frequency of the AC power signal, and the method includes varying the
15 frequency of the AC power signal: to recede from the resonance frequency when the DC power input is determined to have fallen; and, to approach the resonance frequency when the DC power input is determined to have risen.

20 43. A method according to any of claims 39 to 42 including determining an average value of the DC power input to the inverter over a predetermined averaging period, and varying the frequency of the AC power signal according to a difference value being the difference
25 between an instantaneous value of the DC power input and the average value thereof.

44. A method according to Claims 43 including determining the oscillation period of the variations in
30 the DC power input, whereby the predetermined averaging period is of a duration substantially equal to the oscillation period.

45. A method according to any of claims 43 to 44

including storing a plurality of separate and successive of the aforesaid difference values for the purposes of future use in varying the frequency of said AC signal.

5 46. A power controller for controlling the power delivered to a discharge light from a source of direct-current (DC) power, the power being delivered via a signal inverter and subsequent ballast circuit as an alternating (AC) power signal, the power controller
10 including:

control means arranged to monitor variations in the DC power input to the inverter means, and to vary the frequency of the alternating power signal according to detected variations in the DC power input, thereby to
15 control variations in the power supplied to the discharge light via the ballast circuit.

47. A power controller according to Claim 46 in which the control means is arranged to vary the frequency
20 of the AC power signal so as to minimise variations in the power supplied to the discharge light via the ballast circuit.

48. A power controller according to Claim 46 or 47
25 in which the ballast circuit resonates at a predetermined frequency of the AC power signal, and the control means is arranged to vary the frequency of the AC power signal: to recede from the resonance frequency when the DC power input is determined to have fallen; and, to approach from
30 the resonance frequency when the DC power input is determined to have risen.

49. A power controller according to any of Claims

46 to 48 in which the control means is arranged to determine an average value of the DC power input to the inverter over a predetermined averaging period, and to vary the frequency of the AC power signal according to a difference value being the difference between an instantaneous value of the DC power input and the average value thereof.

50. A power controller according to Claim 49 in which the control means is the control means is arranged to determine the oscillation period of the variations in the DC power input, whereby the predetermined averaging period is of a duration substantially equal to the aforesaid oscillation period.

15

51. A power controller according to any of Claims 48 to 50 in which the control means is arranged to store a plurality of separate and successive difference values generated thereby for future use by the power controller in varying said AC signal frequency.

52. A method for controlling the AC power signal supplied to a discharge light via a ballast circuit containing an inductor, including:

monitoring the inductor voltage generated across the inductor in response to the AC power signal, and inputting an excitation pulse signal to the discharge light via the ballast circuit having a frequency substantially equal to, or a multiple of, the resonance frequency of the ballast circuit.

53. A method according to Claim 52 in which the

excitation pulse signal is arranged to cause the ballast circuit to generate a voltage across the discharge light sufficient to maintain the discharge light in a conductive state.

5

54. A method according to Claim 52 or 53 in which the ballast circuit resonates at a predetermined frequency of the AC power signal, wherein the excitation pulse signal is generated to have a frequency being substantially equal in value to the resonance frequency.

10

55. A method according to Claim 54 which includes reversibly adjusting the frequency of the AC power signal so as to be increasingly nearer to the resonance frequency thereby to increasingly reduce the power delivered to, and ultimately radiated by, the discharge light.

15

56. A power controller for controlling the AC power signal supplied to a discharge light from an AC power source via a ballast circuit containing an inductor, the power controller including:

20

control means arranged to monitor the inductor voltage generated across the inductor in response to the AC power signal, and to cause the AC power source to generate an excitation pulse signal for input to the discharge light via the ballast circuit having a frequency substantially equal to, or a multiple of, the resonance of the ballast circuit.

25

30

57. A power controller according to Claim 60 in which the excitation pulse signal is formed to cause the ballast circuit to generate a voltage across the light

sufficient to maintain the plasma excitation voltage thereof.

58. A power controller according to Claim 56 or 57
5 in which the ballast resonates at a predetermined frequency of the AC power signal, wherein the excitation pulse signal is generated to have a frequency being substantially equal in value to the resonance frequency.

10

59. A method for controlling the power delivered to a discharge light in use by an alternating (AC) power signal via a ballast circuit, the method including;

15 monitoring the ambient illumination level in the vicinity of the light, and adjusting the frequency of said alternating power signal to adjust the power delivered to, and ultimately radiated by, the light thereby to maintain the ambient illumination level at a substantially constant value.

20

60. A method according to Claim 59 in which the ballast circuit resonates at a predetermined frequency of the AC power signal, and the control method includes reversibly adjusting the frequency of the alternating
25 output signal so as to approach the value of the resonance frequency thereby to reduce the power delivered to, and radiated by, the discharge light.

61. A power controller for controlling the power
30 delivered to a discharge light in use by an alternating (AC) power signal from an AC power source via a ballast circuit, the controller including;

control means arranged to monitor the ambient illumination level in the vicinity of the light, and to

adjust the frequency of the AC power signal to adjust the power delivered to, and ultimately radiated by, the light thereby to maintain the ambient illumination level at a substantially constant value.

5

62. A power controller according to Claim 61 in which the ballast circuit resonates at a resonance frequency value of the frequency of the AC power signal, and the control means is operable to reversibly adjust the frequency of the AC power signal so as to approach the value of the resonance frequency thereby to reduce the power delivered to, and radiated by, the discharge light.

15 63. A method for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit, the method including;

providing a re-programmable control means operable to process software arranged, when processed, to generate control signals for use in controlling the AC power signal to adjust the power delivered to the discharge light.

25 64. A method according to Claim 63 including monitoring predetermined conditions in the environment of the discharge light, and re-programming according to said conditions whereby the control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

30 65. A method according to Claim 63 or Claim 64 includes re-programming according to a predetermined re-program signal upon receipt of which the control means

modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

5 66. A method according to Claim 65 including remotely reprogramming said control means via a remote re-program signal.

10 67. A method according to Claim 66 including remotely reprogramming said control means wirelessly via said remote re-program signal.

15 68. A method according to Claim 64 including re-programming in response to changes in said predetermined conditions.

20 69. A method according to Claim 64 in which said predetermined conditions include one or more of: a property of said AC power signal; the ambient illumination level at location of the discharge light; the presence within the environment of said discharge light of other said power control means associated with other discharge lights.

25 70. A method for controlling the power delivered to a plurality of discharge lights each of which is separately controlled by a respective separate re-programmable control means according to any of preceding claims 63 to 69 wherein the method includes controlling
30 the separate control means to operate collectively.

71. A method according to Claim 70 including employing any given one of said separate control means to monitor the operating conditions of each of the other of

)
said separate discharge lights and/or respective control means, and re-programming according to said monitored operating conditions whereby the given control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal delivered to the discharge light associated with the given control means.

72. A control apparatus for controlling the power delivered to a discharge light by an alternating (AC) power signal via a ballast circuit, the apparatus including;

a re-programmable control means operable to process software arranged, when processed, to generate control signals for use in controlling the AC power signal to adjust the power delivered to the discharge light.

73. Apparatus according to Claim 72 in which said re-programmable control means is operable to monitor predetermined conditions in the environment of the discharge light, and to re-program according to said conditions whereby the control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

74. Apparatus according to Claim 72 or Claim 73 in which said re-programmable control means is operable to re-program according to a predetermined re-program signal upon receipt of which the control means modifies said software which, when processed thereby, generates accordingly modified control signals for use in controlling the AC power signal.

75. Apparatus according to Claim 74 wherein said control means is arranged to receive a remote re-program signal.

5 76. Apparatus according to Claim 75 wherein said control means is arranged to receive a remote re-program signal wirelessly.

77. Apparatus according to Claim 76 in which said
10 power control means is operable to re-program in response to changes in said predetermined conditions.

78. Apparatus according to Claim 77 in which said
predetermined conditions include one or more of: a
15 property of said AC power signal; the ambient illumination level at location of the discharge light; the presence within the environment of said discharge light of other said power control means associated with other discharge lights.

20

79. Apparatus for controlling the power delivered to a plurality of discharge lights each of which is separately controlled by a respective separate control means of apparatus according to any of preceding claims
25 72 to 78 wherein separate control means are arranged to operate collectively.

80. Apparatus according to Claim 79 in which any given one of said separate control means is operable to
30 monitor the operating conditions of each of the other of said separate control means, and to re-program according to said monitored operating conditions whereby the given control means modifies said software which, when processed thereby, generates accordingly modified control

signals for use in controlling the AC power signal delivered to the discharge light associated with the given control means.

5 81. A method for controlling the alternating (AC) power output signal generated by a signal inverter, including:

separately generating two separate inverter control signals for input to the signal inverter for the control
10 thereof, wherein a first of the two separate inverter control signals is arranged to control the generation of the positive polarity portions of the AC power output signal and a second of the two separate inverter control signals is arranged to control the generation of the
15 negative polarity portions of the AC power output signal.

82. A method according to Claim 81 in which each of said two separate inverter control signals comprises a
20 separate train of control signal pulses and the control method includes generating the successive control signal pulses of the two separate inverter control signals alternately such that any control signal pulse of any one such inverter control signal is generated only if a
25 control signal pulse of the other such inverter control signal is not concurrently in generated.

83. A method according to Claim 82 in which the duration of control signal pulses are controlled thereby
30 to provide a variable dead-time between successively generated such pulses during which no control signal pulse of either of the two separate control signals is generated.

84. A method according to any of Claims 81 to 83 in which each of the two separate inverter control signals comprises a train of control signal pulses, each pulse therein being of a duration which is controlled by the inverter control means and which is less than half the cycle period of the alternating output signal of the inverter, whereby the inverter is responsive to the input thereto of a given control signal pulse so as to generate an output signal pulse of positive polarity in response to the first control signal pulse and to generate an output signal pulse of negative polarity in response to the second control signal pulse.

85. A method according to any of Claims 81 to 84 including separately generating the first and second inverter control signals using separate respective programmable control signal generators each programmable to exist in either an active state in which a generator output is produced thereby, or in an inactive state in which no generator output is produced thereby, whereby an inverter control signal is generated according to the presence and absence of such control signal generator outputs.

86. A method according to Claim 85 which includes successively re-programming each of the control signal generators so as to alternate between an active state and an inactive state.

87. A power controller for controlling the alternating (AC) power output signal generated by a signal inverter, including:

inverter control means arranged to separately generate two separate inverter control signals for input

to the signal inverter for the control thereof, wherein a first of the two separate inverter control signals is arranged to control the generation of the positive polarity portions of the AC power output signal and a second of the two separate inverter control signals is arranged to control the generation of the negative polarity portions of the AC power output signal.

88. A power controller according to Claim 87 in which each of the two separate inverter control signals comprises a train of control signal pulses and the inverter control means is arranged to generate successive control signal pulses of the two separate inverter control signals alternately such that any control signal pulse of any one such inverter control signal is generated only if a control signal pulse of the other such inverter control signal is not concurrently generated, thereby to cause the inverter means to generate the AC power output signal.

20

89. A power controller according to Claim 88 in which the duration of control signal pulses generated by the inverter control means is controlled thereby to provide a variable dead-time between successively generated such pulses during which no control signal pulse of either of the two separate control signals exists.

90. A power controller according to any of Claims 87 to 89 in which each of the two separate inverter control signals comprises a train of control signal pulses, each pulse therein being of a duration which is controlled by the inverter control means and which is less than half the cycle period of the AC power signal,

whereby the inverter is responsive to the input thereto of a given control signal pulse so as to generate an output signal pulse of positive polarity in response to a first control signal pulse and to generate an output
5 signal pulse of negative polarity in response to a second control signal pulse.

91. A power controller according to Claim 90 in which the duration of a given output signal pulse is
10 substantially equal to the duration of the given control signal pulse in response to which the given output signal pulse is generated by said inverter.

92. A power controller according to any of Claims
15 87 to 91 in which the inverter control means includes a first control signal generator means and a separate second control signal generator means arranged to separately generate said first and second inverter control signals respectively, wherein each aforesaid
20 control signal generator means is programmable to exist in either an active state in which a generator output is produced thereby, or in an inactive state in which no generator output is produced, whereby an inverter control signal is generated according to the presence or absence
25 of such generator outputs.

93. A power controller according to Claim 92 in which the inverter control means includes a programming means arranged to successively re-program each of said
30 first and second control signal generator means so as to alternate between an active state and an inactive state.

94. A power controller according to any of Claims

87 to 93 in which the inverter control means is arranged to input the first and second inverter control signals to the inverter means in separate respective control signal input channels.

5

95. A power controller substantially as described in any embodiment hereinbefore with reference to the accompanying drawings.

10

96. A method for controlling power substantially as described in any embodiment hereinbefore with reference to the accompanying drawings.
